## FOREWORD

This, the 191st volume of the Transactions of the American Institute of Mining and Metallurgical Engineers, contains the technical papers of the three Divisions of the Metals Branch published in the Transactions section of the JOURNAL OF METALS in 1951. As initiated in volume 185 and continued in volume 188, the technical papers and discussions of the Institute of Metals, Iron and Steel, and Extractive Metallurgy Divisions are presented under a single cover.

Most of our members are aware of the rather stringent financial circumstances surrounding publication activities of the Institute and especially of the Metals Branch. Substantial progress has been made in ameliorating these difficulties, and particularly in the emergence and growth of the JOURNAL OF METALS with greater advertising revenue.

Papers published in this volume derive from a period of acute retrenchment in the Branch publishing program. They represent the distillate of the distillate. The work of the Divisional publications committees has been arduous in an effort to avoid eliminating any valuable papers, to eliminate any unnecessary wordage or information already available elsewhere, to encourage the submission of shorter papers or technical notes by authors only part of whose work was new or conclusive, and to strive for clarity in the final version of every paper accepted for publication. All readers owe these committees a debt of gratitude.

The Institute of Metals Division, which has suffered the greatest disparity between material available and that for which publication space could be found, has contributed 74 papers. High technical quality of the work will be evident to the reader. The Institute of Metals Division Lecture by Borelius is included in this group.

The Iron and Steel Division is represented by a group of 15 papers ranging from thermodynamics to plant operations. The Howe Memorial Lecture by Vilella is included in this group.

The Extractive Metallurgy Division presents 19 papers. It is particularly encouraging to note the contributions dealing with physical chemistry. Description of plant operations, a subject vital to the quickened professional growth of young engineers, has received modest attention and merits more as Institute income increases and more papers become available.

An expression of thanks and appreciation is due the authors and discussion contributors. We must express our appreciation to the members of the headquarters staff, to the Division officers, and to the members of the various Divisional committees, without whose cooperative efforts this volume could not have come into existence. Finally, we of the metallurgical profession must express our thanks to those companies and institutions which have donated the time required by their author and committee members for preparation of the solid contribution to the literature represented by Volume 191.

DECEMBER 3, 1951  
JOSEPHTOWN, PA.

CARLETON C. LONG, *Chairman*  
Metals Branch Council, AIME

JOURNAL OF METALS was paged consecutively throughout 1951. Thus, in this volume of the Metals Transactions there are 11 interruptions in the pagination. The missing pages appeared in JOURNAL OF METALS. This volume consists of all the Metals Transactions for 1951.

### TECHNICAL PAPERS Institute of Metals Division

|-----------------------------------------------------------------------------------------------------------------------------------------------------|------|
| Metallographic Study of the Martensite Transformation in Lithium. By J. S. BOWLES.....                                                              | 44   |
| Discussion .....                                                                                                                                    | 1056 |
| Plastic Deformation and Diffusionless Phase Changes in Metals—The Gold-Cadmium Beta Phase. By L. C. CHANG and T. A. READ.....                       | 47   |
| Atomic Relationships in the Cubic Twinned State. By W. C. ELLIS and R. G. TREUTING.....                                                             | 53   |
| Discussion .....                                                                                                                                    | 1070 |
| Transitions in Chromium. By M. E. FINE, E. S. GREINER, and W. C. ELLIS.....                                                                         | 56   |
| Discussion .....                                                                                                                                    | 1066 |
| Effect of Heat Treatment on the Electrical Properties of Germanium. By H. C. THEUERER and J. H. SCAFF.....                                          | 59   |
| Aging of Sand-Cast Mg-Al-Zn Alloys. By T. E. LEONTIS and C. E. NELSON.....                                                                          | 120  |
| Mechanical Properties of Stainless Steel Powder. By ARTHUR H. GROBE and GEORGE A. ROBERTS.....                                                      | 125  |
| Discussion .....                                                                                                                                    | 1076 |
| Cobalt Self-Diffusion: A Study of the Method of Decrease in Surface Activity. By R. C. RUDER and C. E. BIRCHENALL.....                              | 142  |
| Formation and Behavior of Subboundaries in Silicon Iron Crystals. By C. G. DUNN and F. W. DANIELS.....                                              | 147  |
| Interface and Marker Movements in Diffusion in Solid Solutions of Metals. By LUIZ C. CORREA DA SILVA and ROBERT F. MEHL.....                        | 155  |
| Discussion .....                                                                                                                                    | 1060 |
| Effect of Ternary Additions on the Age-Hardening of a Copper-Silver Alloy. By HAROLD MARGOLIN and WALTER R. HIBBARD, JR. (Correction, p. 464).....  | 174  |
| Microscopic Observation of the Solidification of Cu-Ni Alloy Droplets. By R. E. CECHE and D. TURNBULL.....                                          | 242  |
| Solubility of Hydrogen in Molten Lead. By W. R. OPIE and N. J. GRANT (Correction, p. 528).....                                                      | 244  |
| Intergranular Energy of Iron and Some Iron Alloys. By LAWRENCE H. VAN VLACK.....                                                                    | 251  |
| Discussion .....                                                                                                                                    | 1067 |
| Constitution of Iron-Chromium-Molybdenum Alloys at 1200°F. By SPENCER R. BAEN and POL DUWEZ.....                                                    | 331  |
| Effect of Alloying Elements on True-Stress True-Strain Flow Curves of Pearlitic Steel. By R. RARING, J. A. RINEBOLT, and W. J. HARRIS, JR.....      | 395  |
| Discussion .....                                                                                                                                    | 1065 |
| Effects of Precompression on the Behavior of the Aluminum Alloy 24ST4 During Cyclic Direct Stressing. By S. I. LIU.....                             | 452  |
| Effect of Alloying Elements on the Electrical Resistivity of Aluminum Alloys. By A. T. ROBINSON and J. E. DORN.....                                 | 457  |
| Growth of Molybdenum Single Crystals. By N. K. CHEN, R. MADDIN, and R. B. POND.....                                                                 | 461  |
| Kinetics of Precipitation in Supercooled Solid Solutions. By G. BORELIUS (Institute of Metals Division Lecture) (Correction, p. 1008).....          | 477  |
| Ignition Temperatures of Magnesium and Magnesium Alloys. By W. MARTIN FASSELL, JR., LEONARD B. GULBRANSEN, JOHN R. LEWIS, and J. HUGH HAMILTON..... | 522  |
| Discussion .....                                                                                                                                    | 1075 |
| Rate of Sintering of Copper Under a Dead Load. By F. N. RHINES and H. S. CANNON.....                                                                | 529  |
| Discussion .....                                                                                                                                    | 1076 |
| Observations on Cleavage and Polygonization of Molybdenum Single Crystals. By NENG-KUAN CHEN and ROBERT MADDIN.....                                 | 531  |
| Secondary Recrystallization in Copper Wire. By GUIDO BASSI.....                                                                                     | 533  |
| Powder Metallurgy of Zirconium. By HENRY H. HAUSNER, HERBERT S. KALISH, and ROSWELL P. ANGIER.....                                                  | 625  |

| Creep and Stress Rupture Behavior of Aluminum as a Function of Purity. By ITALO S. SERVI and NICHOLAS J. GRANT                                                     | 909  |
| Structure Observations of Aluminum Deformed in Creep at Elevated Temperatures. By ITALO S. SERVI and NICHOLAS J. GRANT                                             | 917  |
| Solubility Relationships in Some of the Ternary Systems of Refractory Monocarbides. By JOHN T. NORTON and A. L. MOWRY                                              | 923  |
| High Temperature Oxidation of Copper-Palladium and Copper-Platinum Alloys. By D. E. THOMAS                                                                         | 926  |
| Plasticity of Molybdenum Single Crystals. By N. K. CHEN and R. MADDIN                                                                                              | 937  |
| Work Hardening-Reannealing Cycle of Pure Silver. By MARIAN BALICKI and GOLDFEED LEEDS                                                                              | 981  |
| Effect of Rare-Earth Metals on the Properties of Extruded Magnesium. By T. E. LEONTIS                                                                              | 987  |
| Preferred Orientation in Zirconium. By R. K. McGEARY and B. LUSTMAN                                                                                                | 994  |
| Grain-Growth and Recrystallization Characteristics of Zirconium. By F. J. DUNKERLEY, F. PLEDGER, V. DAMIANO, and J. FULTON                                         | 1003 |
| Discussion                                                                                                                                                         | 1008 |
| Chromium-Nickel Phase Diagram. By DAVID S. BLOOM and NICHOLAS J. GRANT                                                                                             | 1009 |
| Free Energy of Formation of Cementite and the Solubility of Cementite in Austenite. By L. S. DARKEN and R. W. GURRY                                                | 1015 |
| Habit Phenomenon in the Martensitic Transformation. By E. S. MACHLIN and MORRIS COHEN                                                                              | 1019 |
| Mechanism of Grain Refinement in Aluminum Alloys. By F. A. CROSSLEY and L. F. MONDOLFO                                                                             | 1143 |
| Constitution of Titanium-Aluminum Alloys. By H. R. OGDEN, D. J. MAYKUTH, W. L. FINLAY, and R. I. JAFFEE                                                            | 1150 |
| Model for Dendrite Growth Form in Metals and Alloys. By R. B. POND and S. W. KESSLER                                                                               | 1156 |
| Solubility of Gaseous Nitrogen in Gamma Iron and the Effect of Alloying Constituents—Aluminum Nitride Precipitation. By L. S. DARKEN, R. P. SMITH, and E. W. FILER | 1174 |
| Effect of Varying the Rate of Reduction on the Magnetic Properties, Ultimate Tensile Strength, and Resistivity of 18/8 Stainless Steel Wire. By SAMUEL STORCHHEIM  | 1181 |
| Correlation Between Electrical Conductivity and Temperature Coefficient of Resistance of Solid-Solution Alloys. By M. HANSEN, W. R. JOHNSON, and JOHN M. PARKS     | 1184 |
| Metallurgical Mechanism for Mercury Stress Cracking of Copper Alloys. By W. D. ROBERTSON                                                                           | 1190 |
| Vapor Pressures of Zinc Over AgZn Alloys. By E. E. UNDERWOOD and B. L. AVERBACH                                                                                    | 1198 |
| Analytical Representation of Certain Phase Boundaries. By W. ROSTOKER                                                                                              | 1203 |
| Surface Tension of Solid Silver. By E. R. FUNK, H. UDIN, and J. WULFF                                                                                              | 1206 |
| Surface Tension of Solid Gold. By F. H. BUTTNER, H. UDIN, and J. WULFF                                                                                             | 1209 |

## Iron and Steel Division

|                                                                                                                                                            |      |
|------------------------------------------------------------------------------------------------------------------------------------------------------------|------|
| Solution Loss and Reducing Power of Blast Furnace Gas. By T. L. JOSEPH                                                                                     | 37   |
| Discussion                                                                                                                                                 | 1053 |
| Observations on Rimming Steel Ingots. By A. HULTGREN, G. PHRAGMEN, S. WOHLFAHRT, and J. E. OSTBERG. (Correction, p. 464)                                   | 101  |
| Vanadium-Oxygen Equilibrium in Liquid Iron. By JOHN CHIPMAN and MINU N. DASTUR                                                                             | 111  |
| Desulphurizing Molten Iron with Calcium Carbide. By S. D. BAUMER and P. M. HULME                                                                           | 313  |
| Discussion                                                                                                                                                 | 1051 |
| Distribution of Sulphur Between Liquid Iron and Slags of Low Iron-Oxide Concentrations. By R. ROCCA, N. J. GRANT, and J. CHIPMAN                           | 319  |
| Discussion                                                                                                                                                 | 1050 |
| A Thermodynamic Study of the Reaction $CaS + H_2O \rightleftharpoons CaO + H_2S$ and the Desulphurization of Liquid Metals with Lime. By TERKEL ROSENQVIST | 535  |
| Discussion                                                                                                                                                 | 1047 |
| Twenty-Five More Years of Metallography. By J. R. VILELLA. (Howe Memorial Lecture)                                                                         | 605  |

|                                                                                                                                              |      |
|----------------------------------------------------------------------------------------------------------------------------------------------|------|
| Effects of Manganese and Its Oxide on Desulphurization by Blast-Furnace Type Slags. By NICHOLAS J. GRANT, ULF KALLING, and JOHN CHIPMAN..... | 666  |
| Discussion.....                                                                                                                              | 1048 |
| Effect of Silica Reduction on the Desulphurizing Power of Blast-Furnace Type Slags. By NICHOLAS J. GRANT, OLAF TROLLI, and JOHN CHIPMAN..... | 672  |
| Discussion.....                                                                                                                              | 1049 |
| Desulphurizing Action of Titanium in Steels. By W. P. FISHEL, WILLIAM P. ROE, and JAMES F. ELLIS.....                                        | 674  |
| Desulphurization of Pig Iron with Pulverized Lime. By Bo KALLING, C. DANIELSSON, and OTTAR DRAGGE.....                                       | 732  |
| Discussion.....                                                                                                                              | 1052 |
| Kalling-Domnarfvet Process at Surahammar Works. By SVEN FORNANDER.....                                                                       | 739  |
| Discussion.....                                                                                                                              | 1052 |
| A Corrected CO/CO <sub>2</sub> Ratio for Blast Furnaces. By SID T. KILLIAN.....                                                              | 742  |
| Low Sulphur Steel from High Sulphur Raw Materials and Fuel. By F. L. ROBERTSON, C. H. BACON, and J. W. TILL.....                             | 1031 |
| Discussion.....                                                                                                                              | 1043 |
| A Survey of the Sulphur Problem Through the Various Operations in the Steel Plant. By T. E. BROWER and B. M. LARSEN.....                     | 1163 |

### Extractive Metallurgy Division

|                                                                                                                               |      |
|-------------------------------------------------------------------------------------------------------------------------------|------|
| Industrial Hygiene at American Smelting and Refining Company. By JOHN N. ABERSOLD and K. W. NELSON. (Correction, p. 146)..... | 33   |
| Sintering Practice at Josephtown Smelter. By H. K. NAJARIAN, KARL F. PETERSON, and ROBERT E. LUND.....                        | 116  |
| Discussion.....                                                                                                               | 1045 |
| Preparation of Titanium Tetrachloride from Rutile. By C. H. GORSKI.....                                                       | 131  |
| Reverse Leaching of Zinc Calcine. By L. P. DAVIDSON, R. K. CARPENTER, and H. J. TSCHIRNER.....                                | 134  |
| Metallurgical Reactions of Fluorides. By HERBERT H. KELLOGG.....                                                              | 137  |
| Discussion.....                                                                                                               | 1046 |
| El Paso Refinery of Phelps Dodge Refining Corporation. By B. B. KUNKLE.....                                                   | 229  |
| Sulphur Activities in Liquid Copper Sulphides. By R. SCHUHMAN and O. W. MOLES.....                                            | 235  |
| Vacuum Treatment of Parkes' Process Crusts on a Pilot-Plant Scale. By A. W. SCHLECHTEN and R. F. DOEL-LING.....               | 327  |
| Extraction of Alumina from Haiti and Jamaica Bauxites. By T. D. TIEMANN.....                                                  | 389  |
| Thermodynamics of Iron-Silicate Slags: Slags Saturated with Gamma Iron. By R. SCHUHMAN, JR. and P. J. ENSIO.....              | 401  |
| Discussion.....                                                                                                               | 1046 |
| Metallurgy of Cobalt Production from Cupriforous Pyrite. By SANAI NAKABE.....                                                 | 445  |
| Relationships Between Germanium and Cadmium in the Electrolysis of Zinc Sulphate Solutions. By S. T. ROSS and J. L. BRAY..... | 465  |
| Electric Furnace Melting of Copper at Baltimore. By PETER R. DRUMMOND.....                                                    | 468  |
| Separation of Copper from Zinc by Ion Exchange. By ERNEST J. BRETON, JR. and A. W. SCHLECHTEN.....                            | 517  |
| Arc Melting of Titanium Metal. By S. F. RADTKE, R. M. SCRIVER, and J. A. SNYDER.....                                          | 620  |
| Discussion.....                                                                                                               | 1046 |
| Production of Aluminum from Kalunite Alumina. By ARTHUR FLEISCHER and JULIAN GLASSER.....                                     | 634  |
| Recovery of Vanadium from Titaniferous Magnetite. By SANDFORD S. COLE and JOHN S. BREITENSTEIN.....                           | 1133 |
| Low Grade Bauxites and Clays as Potential Aluminum Resources. By K. K. KERSHNER, C. W. FUNK, and W. A. CALHOUN.....           | 1138 |
| Rate of Evaporation of Zinc at Low Pressures. By H. W. ST. CLAIR and M. J. SPENDLOVE.....                                     | 1192 |

### TECHNICAL NOTES

|                                                                                                                                        |      |
|----------------------------------------------------------------------------------------------------------------------------------------|------|
| Grain Boundary Effect in Surface Tension Measurement. By HARRY UDIN.....                                                               | 63   |
| Crystallographic Angles for Magnesium, Zinc, and Cadmium. By EDWARD I. SALKOVITZ (Correction, p. 880).....                             | 64   |
| "Oriented Growth" in Primary Recrystallization. By JOSEPH J. BECKER.....                                                               | 115  |
| Surface Diffusion in Sintering of Spheres on Planes. By P. SCHWED.....                                                                 | 245  |
| Re-solution of Precipitated Silver in Copper-Silver Alloys. By HAROLD MARGOLIN and WALTER R. HIBBARD, JR. ....                         | 247  |
| Fractographic Pattern for 475°C Embrittlement in Stainless Steel. By CARL A. ZAPFFE.....                                               | 247  |
| Structure of Spherulites in Nodular Cast Iron. By H. E. STAUSS, F. W. VON BATCHELDER, and E. I. SALKOVITZ.....                         | 249  |
| Deformation and Recrystallization Texture of Cold-Drawn OFHC Copper Wire. By W. A. BACKOFEN.....                                       | 250  |
| Precipitation and Diffuse Scattering in an Fe-Mo-Co Alloy. By A. H. GEISLER and F. E. STEIGERT.....                                    | 259  |
| Titanium-Boron Alloys. By H. R. OGDEN and R. I. JAFFEE.....                                                                            | 335  |
| Structure of the Yellow Crystalline Fraction of Blast-Furnace Salamander. By JOHN R. WEEKS, DAN McLACHLAN, JR., and JOHN R. LEWIS..... | 393  |
| Some Notes on the Barley Shell Structure in Iron-Silicon Alloys. By R. V. RILEY.....                                                   | 412  |
| Deformation Texture of Cold-Drawn Copper Wire. By WALTER R. HIBBARD, JR. ....                                                          | 467  |
| Metallographic Techniques for High Purity Aluminum. By ITALO S. SERVI and NICHOLAS J. GRANT.....                                       | 473  |
| Origin of the Cube Texture in Face-Centered Cubic Metals. By PAUL A. BECK.....                                                         | 474  |

# Industrial Hygiene At American Smelting and Refining Company

by John N. Abersold and K. W. Nelson

**I**NDUSTRIAL hygiene has been defined by Patty<sup>1</sup> as "the science and art of recognizing, evaluating, and controlling potentially harmful factors in the industrial environment." This definition implies thorough study of operations, evaluation of potentially harmful factors through air sampling, micro-analyses and other means, and, finally, appropriate medical and engineering control wherever indicated.

The prevention of industrial health injuries is a vital part of operations of American industry today. Progress and interest in this field has increased steadily for many years, the most rapid progress having been attained, perhaps, during the last three decades. It is significant to note that there are now official agencies in 46 states actively concerned with industrial health problems and that a western field station has been established recently in Salt Lake City by the U. S. Public Health Service to augment its industrial hygiene services directed from headquarters of the National Institute of Health, Bethesda, Md. Many of the larger industries have found it advantageous to establish their own industrial hygiene departments.

The American Smelting and Refining Co. is a world-wide organization engaged in the mining, smelting, and refining of lead, copper, zinc, silver, gold, by-product metals, including cadmium, arsenic, and others. In the United States there are 13 smelters and refineries, 11 secondary smelters or foundries, and a number of mines. Approximately 9000 workers are normally employed.

It has long been the established company policy to seek out occupational hazards and provide safeguards for employee health. Protective equipment has been supplied to individual workers and exhaust ventilation installations have been in use in some operations for more than 40 years. All of the major units have their own medical departments which provide employees with excellent medical and hospital care.

In 1937 full scale industrial hygiene studies were undertaken at the Selby Plant and were extended to most of the other smelters during the next three years. In 1945 the Department of Hygiene was organized with Professor Philip Drinker of Harvard University as Director and with Dr. S. S. Pinto as Medical Director. The department is responsible for coordinating and maintaining a program for the good health of all employees from top management down to the lowest paid day worker. It is essentially a service organization serving all of the United States plants regardless of location or size. Full and part-time physicians employed in all of the company's American plants and working in close cooperation with the Medical Director are responsible for de-

termining the state of health of all the employees and giving treatment when necessary. In general, medical care is confined to accidents or illnesses occurring while the men are on the job. Among the duties of the doctors is the making of careful physical examinations of new employees and routine check-ups of old employees.

In addition to medical care a primary responsibility of the department is the *prevention* of occupational illnesses. In this the main concern is with the working environment in relation to its effect on the worker. Environmental factors may be dusts, fumes, gases, toxic materials, heat, humidity, radiation, or noise. The objectives are: (1) Immediate control of these factors through the education of the worker, through providing the wearing of respirators or other protective devices, and through careful medical examinations and regular analysis of urine specimens; (2) a long range control program which may be accomplished by local exhaust ventilation, wetting of materials, changes in metallurgy, changes in methods of handling, or by use of special devices and special equipment.

To accomplish these objectives a fine industrial hygiene laboratory was built in Salt Lake City and equipped to do routine and experimental work. Trained and experienced industrial hygienists obtain the facts by making frequent hygiene surveys. These surveys include tests of the air, studies of all processes, and careful investigation of ventilation, lighting, and general working conditions. Except in emergencies, the air contaminants and often the substances handled by the worker are sent to the laboratory for analysis by chemists and technicians specially trained in industrial hygiene methods. The findings are evaluated in terms of limits recommended by various State and Federal agencies, and in light of all available medical data.

The methods used for studying the working environment involve all of the usual chemical and physical procedures employed in industrial hygiene. The Impinger, electric precipitator, thermal precipitator, and filter paper sampler have been used to collect atmospheric dust and fume samples. Of special interest here is the filter paper sampler, shown in Fig. 1, which was developed by Dr. Silverman at Harvard University. The instrument has been improved and is used very extensively in field studies. A water manometer connected behind an orifice is used to determine the rate of air flow. Calibration is effected by use of a standard gas meter or rotameter. The dust or fume is collected on a filter paper clamped between two rings, as shown in Fig. 2. The filter paper, such as Whatman No. 52, collects both dust and fume with a very high efficiency. The instrument is very convenient and easily transported.

The solids collected on the filter paper are analyzed in the laboratory usually by use of a polarographic procedure. By this procedure it is possible to measure quantitatively in a single analysis the

JOHN N. ABERSOLD, Chief Hygienist and K. W. NELSON, Hygienist, Dept. of Hygiene, American Smelting and Refining Co., Salt Lake City, Utah.

Fig. 1—Filter paper sampling apparatus ready for use.

copper, lead, cadmium, and zinc in each sample. Polarographic methods are also used for the determination of a number of other elements.

Dusts of various types are the most common contaminants found in the atmosphere of the various plants. Fumes containing lead oxide may be found in certain smelter and refinery work areas and are given special attention since lead oxide is more readily absorbed than other less soluble lead compounds, such as the sulphide. Other contaminants such as carbon monoxide, hydrogen sulphide, sulphur dioxide, selenium, tellurium, cadmium, and arsenic may be found and require study. Certain of the gases mentioned may be toxic or irritant. In order to be constantly on the alert and to be warned in advance, rapid field tests have been developed for hydrogen sulphide, chlorine, and arsine from a basic British method. In this method a small hand pump is used to draw air through filter paper disks impregnated with various reagents which produce a stain if traces of gas are present, see Fig. 3. These stains are compared with standards to estimate the gas concentrations. By use of this method chemists and safety directors are able to check the working environment for suspected dangers. For one plant where hydrogen sulphide is being used in one of its operations, a machine is being developed to sound automatically an alarm before any escaping gas reaches dangerous concentrations.

From time to time certain analyses requiring highly specialized training or very expensive equipment are performed by the research laboratory or outside laboratories; for example, spectrographic and petrographic analyses. Certain types of research work involving animal experimentation have been performed through grants to Harvard University.

As a part of the fact-finding function of the Hygiene Department, urine specimens and frequently blood specimens are obtained from all workers exposed to lead and other metals and examined at

Fig. 2—Sampling apparatus unassembled.

the Hygiene Laboratory. These tests indicate what the worker has been breathing, usually long before illness occurs. During the past year more than 5000 determinations for lead in urine were made. On the basis of these and other medical findings, the Medical Director may make recommendations for immediate protection of the employee.

The evaluation of all findings is an important function of the Hygiene Department. This involves in part an appraisal of air studies and the correlation of these studies with medical data. When all the facts are brought together, an overall evaluation of the environment is made, the need for control measures determined, and a coordinated control program outlined. Recommendations for control are made to the plant manager and passed on to engineers especially trained in industrial hygiene ventilation. The plant manager and the superintendent with his operating staff decide what method of control should be carried out. This is logical because control may be accomplished by changes

Fig. 3—Sampling pumps and standard stains for field determinations of hydrogen sulphide and chlorine.

in metallurgy or methods of handling rather than by local exhaust ventilation or other engineering or chemical means. Occasionally control is not possible by engineering means and it is necessary to rely on respiratory protective devices and medical control procedures. Sometimes the recommendations for plant improvements are based on comfort alone rather than a health hazard.

The ventilation engineers form a unit or a division of the Western Engineering Department but work in the closest cooperation with the Hygiene Department in carrying out the detailed recommendations. Frequent conferences are held with these engineers and general plans are approved.

### Plant Improvements

Elimination or control of all potentially harmful factors in the environment is the major long-range objective. Since 1938, and particularly during the past four years, much progress has been made toward this objective. In some cases, such as in the mills, the cost has been very high—from ten to twenty thousand dollars per worker. Following are some of the highlights of control of dusts, fumes, and gases in the various plants achieved through the combined interest and effort of managers, superintendents, metallurgists, foremen, the specially trained staff of ventilation engineers of the Western

Engineering Department and the Department of Hygiene:

**Mills:** Wetting has long been used to control dusts in mills. However, because wetted materials in some cases clog up screens and chutes and hinder proper cleaning of equipment between ore lots, other means of control have had to be used also, chiefly local exhaust ventilation and dust collection by small bag-house units and centrifugal impingement washers. Because of the very high cost, experimental work has been conducted to find other methods. Mist-sprays produced by atomizing water with compressed air have been tried. The minute droplets of water produced by these sprays actually wet dust particles and help to reduce the escape of dusts at the source, yet they avoid objectionable wetting of the flowing material. With this method of control a 50 pct reduction in dust concentrations has been achieved in one mill.

In certain instances protection of the worker has been accomplished by ventilating and air conditioning small areas where men work, such as crane cabs, when the general ventilation of the room would be difficult if not impossible, see Stevenson.<sup>2</sup> In other words, the man has been "ventilated" instead of the operation. Cabs of cranes handling ores, carrying hot metals over furnaces, etc., are examples. This approach is being tried now in mills by building booths kept under positive pressure with filtered air for workers whose duties can be carried out from such an enclosure.

**Sampling Rooms:** Local exhaust ventilation and good housekeeping have been used exclusively to control dusts in sampling rooms, see Fig. 4. Modern grinding and sampling equipment are easily enclosed and the dust can be controlled at a very moderate cost.

**Beds and Charge Bins:** Wetting, enclosure and local exhaust ventilation are being used for control of dusts in such equipment. Dust control in these departments is one of the most difficult problems. Wetting can only be used to a limited degree because excess moisture may affect the roasting of certain types of charges.

The unloading of truckloads of ores and concentrates for storage or making up charges was a difficult problem to control in one plant. The final solution was found in a semi-enclosure and hood with high volume air intake.

Fig. 4—Ore sample being screened at bucking table with use of exhaust ventilated hood.

Fig. 5—Workers removing wetted dust from wind boxes of a first-over Dwight-Lloyd sinter machine.

**Dwight-Lloyd Sinter Plants:** Wetting, enclosure and local exhaust ventilation have been the principal methods of controlling dust and fume in the Dwight-Lloyd sinter plants. Water may be added to both first and second-over charges at the belt tripper, at the mixing tables and sometimes with use of pug-mills. Water is used to quench the sinter after it is roasted and the discharge ends of the machines are kept tightly enclosed.

The control of dusts from crushing first-over sinter has been effected with local exhaust ventilation and collection of dusts with centrifugal impingement washers.

The dustiest Dwight-Lloyd operation is the removal of deposits from wind boxes. Control of these dusts has been effected by (1) use of enclosed pan or screw conveyor along wind boxes with draft maintained on the boxes, (2) wetting by inserting into the dust piles a water pipe with flowing water and (3) maintenance of a water seal in the bottom of the wind boxes which completely wets the accumulating dusts. In Fig. 5 is shown the absence of visible dusts after wetting with inserted water pipes. The water seal has been applied only to second-over machines.

Good housekeeping with frequent wash down of floors is very important in control of dusts. Thermal air currents plus vibration can redisperse settled dusts.

Considerable improvement in dust and fume concentrations was effected in one Dwight-Lloyd plant by a change in metallurgy, that is, a lowering of the percentage of coke in the charge.

Excessive heat has been controlled by insulating wind boxes and air ducts and by use of large hoods mounted over the pallet immediately behind burners and connected to a stack for gravity ventilation.

**Lead Blast Furnaces:** The make up of blast furnace charges may involve dusty operations if the second-over sinter is not sufficiently wetted. The sinter is usually stored in hoppers and it has been found necessary to provide exhaust ventilation when the sinter is withdrawn.

The control of dust and fume at the feed to the blast furnace is accomplished chiefly by good draft on the furnace.

The lead blast furnace cannot be tapped for slag, or for lead if the temperature is high, without the generation of much lead fume. Fume from these points is controlled with local exhaust ventilation at all furnaces. It is necessary to raise and lower these hoods occasionally and workers have sometimes neglected this duty because of the little extra work

Fig. 6—Lead and slag being tapped from a blast furnace with use of an improved exhaust ventilated hood.

required. To overcome this and provide heavier construction to resist the heat, a hood has been very recently designed which can be raised and lowered by an electric motor merely by pressing a button as shown in Fig. 6. Stand-by empty or filled lead pots sometimes cause considerable fume. To control this an exhaust ventilated hood with a flexible fireproof duct has been developed.

**Reverberatory Furnaces:** Control of dust and fume from operation of lead dross reverberatory furnaces has been effected by adequate draft on furnaces to prevent escape of fume at the charge door and by local exhaust ventilation at the tap holes and launders for speiss and matte.

**Kettles:** One of the most difficult problems has been control of dusts and fume from refining operations in kettles. Complete or partial hoods with exhaust ventilation have been effective where metals are transferred to kettles or when stirring is done to separate drosses. Fig. 7 shows a partial hood with a high volume air intake to control the fume over the surface of a lead kettle. As another approach to reducing dustiness during dross skimming, experimental work is now under way to (1) change the metallurgy, (2) remove drosses with a screw-type conveyor with local exhaust ventilation at point of discharge into skip and (3) use of a high velocity slot type exhaust around edge of kettle. A fair degree of success has been achieved with use of the screw-type conveyor.

**Flues:** The removal of settled dusts from flues has

Fig. 7—Partial hood with high volume air intake over a lead kettle for control of lead fume.

long been a dusty and unhygienic operation. To control the dusts from this operation, engineers and metallurgists from the Federal Plant<sup>3</sup> developed the telescopic tube device shown in Fig. 8. This device serves as an enclosure and wetting chamber combined. A circular water spray located near the top partially wets the dusts as they pass from flue to car. The wetting of the dusts is continued in the car and minimizes dusting in later handling.

**Cottrells:** The control of atmospheric dusts resulting from the cleaning of cottrell hoppers has been difficult. Enclosed and ventilated conveyors along hoppers have not been adequate. Spills which create airborne dusts do occur in spite of the best care. The problem has finally been solved by replacing the workers with automatic equipment. Electric vibrating hammers have now been installed on most of the cottrell units.

**By-Products Metals:** The control of dusts and gases in the refining and packaging of by-product

Fig. 8—Workmen extracting flue dust with use of telescopic tube device designed for control of dusts by wetting and enclosure.

elements, such as selenium, tellurium, and cadmium, has been accomplished by use of local exhaust ventilation almost exclusively.

The hygiene program and some of the work that has been done to improve working conditions in the American Smelting and Refining Co. have been reviewed briefly. In presenting this information there is no wish to convey the impression all objectives have been reached. There are problems yet to solve, and changes in operations and new processes continually arise which require study and control. In one smelter recently the minutest details of control in a new process were worked out before the plant was built in order that no chances would be taken. Top management and operating staffs displayed keen interest and cooperated to the fullest extent. The same interest and cooperation from managements of all plants have existed in all other phases of the industrial hygiene program and are largely responsible for what measure of success has been achieved.

# Solution Loss and Reducing Power Of Blast Furnace Gas

by T. L. Joseph

A study is made of the amount of solution loss necessary to maintain the reducing power of the gas stream in the blast furnace. Curves are presented to show the effect of solution loss, moisture in the blast, and carbon dioxide from the flux on the nitrogen in the top gas.

THE blast furnace process is based upon the counter flow of gases and solids. As CO, N<sub>2</sub> and H<sub>2</sub> flow upward from the combustion zones, oxygen is acquired from the descending charge. In the reduction of iron ore, a portion of CO is converted to CO<sub>2</sub> and similarly a portion of H<sub>2</sub> is converted to water vapor. The inert N<sub>2</sub>, from the air used in combustion, passes through the furnace with little change. Its concentration is, however, decreased by reactions such as direct reduction and solution loss which increase the volume of CO in the gas stream. Similarly the evolution of CO<sub>2</sub> from the limestone also dilutes the nitrogen.

The purpose of this paper is to illustrate an idealized and simplified method of studying furnace processes by following changes in the gas phase between the tuyeres and the stock line. A more specific objective is to evaluate the effect of solution loss upon the CO/CO<sub>2</sub> ratio in that region of the furnace in which FeO is reduced to metallic iron. This last stage of reduction requires relatively high CO/CO<sub>2</sub> ratios to exceed the equilibrium requirements. Solution loss or the reaction of CO<sub>2</sub> with C to produce CO has a pronounced effect upon the ratio of the carbon gases and is necessary to maintain the reducing power of the gas stream if the consumption of coke is low. It will be explained later that indirect reduction followed by solution loss is stoichiometrically equivalent to direct reduction.

Calculations will be made to show how the composition of the gas in the region of the mantle varies with coke consumption and with different amounts of solution loss. Such calculations show the condi-

tions under which gasification of C with oxygen in the charge is needed to maintain the reducing power of the gas. Equilibrium conditions for FeO and the carbon gases will be used to establish a minimum CO/CO<sub>2</sub> ratio below which reduction will not proceed. The manner in which carbon is gasified in the furnace, at the tuyeres with oxygen in the air or above the tuyeres with oxygen from the charge, will be a basic feature of all calculations. It is hoped that greater interest in the use of top gas as a means of following furnace reactions will be aroused by the calculations and generalized curves which are presented.

## Bosh Gas Equations

Subject to some alteration by the amount of moisture in the blast and by direct reduction, the gas leaving the combustion zones of a blast furnace has a definite composition. Because a relatively small amount of oxygen is acquired from the charge in the bosh and in the crucible, the products of combustion undergo little change until they enter the shaft. Bosh gas is, therefore, essentially the products of combustion of carbon in a deep fuel bed with air. The relative weights and volumes of reacting materials are expressed by the equation:

$$\left( \text{air} = \frac{79\% N_2}{21\% O_2} = 3.76 \right)$$

Starting with a known mass of C consumed largely by air, Eq 1, but partly by water vapor, Eq 2, the volume and

composition of the bosh gas can be calculated and subsequent changes followed as reactions take place at various elevations in the furnace. As shown in

T. L. JOSEPH, Member AIME, is Professor of Metallurgy, University of Minnesota, Minneapolis.

Discussion of this paper, TP 2981C, may be sent (2 copies) to AIME by April 1, 1951. Manuscript, July 24, 1950; St. Louis Meeting, February 1951.

Fig. 1, bosh gas is converted to intermediate gas which in turn is converted to top gas.

## Changes in Composition of Gas Stream

The reactions that produce the major changes in the gas stream are given in Fig. 2 in terms of pound mols,\* a convenient unit of volume as well as of mass. Except for the amount of carbon burned at

Fig. 1—Major changes in composition of blast furnace gas.

the tuyeres the items reported in Table I are available from routine operating data. A method of calculating the pounds of carbon consumed at the tuyeres has been published.<sup>1</sup>

In setting up the equations and the material balance presented in Fig. 2, it has been assumed that 1086 lb or 90.5 mols of C are gasified at the tuyeres with the moist blast and that 208 lb or 17.33 mols are gasified above the tuyeres with oxygen from the charge. Once the carbon consumed at the tuyeres is fixed, the volume of air required is fixed. In this case, 209.44 lb mols or 79,500 ft<sup>3</sup> of dry air is needed to consume 88 mols of carbon. (379.4 ft<sup>3</sup>/lb mol  $\times$  209.44 lb mols = 79,500 ft<sup>3</sup>).

With a moisture content of about 4 grains per ft<sup>3</sup>, this volume of air will contain 2.5 mols of water which will consume 2.5 mols, or 30 lb, of carbon.

Subject to slight modification by the amount of moisture in the blast and by the CO produced by direct reduction or solution loss in the crucible, the composition of the gas leaving the combustion zones will conform rather closely to that given under bosh gas in Fig. 2. The total volume of gas issuing from

the combustion zones per ton of iron produced will vary with the carbon gasified at the tuyeres. In this case 98,000 ft<sup>3</sup> of gas containing 35 pct CO, 64 pct N<sub>2</sub>, and 1 pct H<sub>2</sub> are formed per ton of iron. At the inward extremities of the combustion zones and particularly in the central idle core where gas flow is restricted, the CO may be higher and the N<sub>2</sub> lower than given in Fig. 2.

A relatively small amount of CO, 2.5 mols or 950 ft<sup>3</sup>, is formed during the reduction of MnO, SiO<sub>2</sub>, and P<sub>2</sub>O<sub>5</sub> in the bosh and in the crucible. There is no way of knowing what proportion of the metalloids is reduced in the hearth. For simplicity, it is assumed that most of the CO from direct reduction enters the gas stream in the bosh.

## Change from Bosh Gas to Intermediate Gas

The term bosh gas refers to the gas formed in the high-temperature combustion zones adjacent to the tuyeres. Because a comparatively small amount of oxygen is removed from the charge in the bosh, the gas stream undergoes little change in this part of the furnace. Near the top of the bosh and in the lower part of the shaft a number of reactions take place because all of them proceed at temperatures ranging from 1100°C down to 800°C. Ferrous oxide is reduced, the limestone calcines, and CO<sub>2</sub>, either from calcination or from indirect reduction, reacts with carbon according to the solution loss reaction. These reactions representing the acquisition of oxygen from the charge as CO and CO<sub>2</sub> are summarized in Fig. 2.

As indicated in Table I, a net ton of pig iron will contain about 1840 lb of Fe equivalent to 2374 lb or 33.05 mols of FeO. It is arbitrarily assumed that one half the H<sub>2</sub> from the combustion zone reacts with 1.25 mols of FeO, and that the remaining 31.80 mols of FeO are reduced with CO. The amount of H<sub>2</sub> involved in reduction is normally relatively small but

additions of steam to the blast could lead to a substantial reduction in the amount of CO<sub>2</sub> formed and in the ratio of the carbon gases.

By making appropriate adjustments for the carbon gasified in the reduction of metalloids, and for the carbon dissolved in the iron, it is possible to determine the weight of carbon gasified above the

\* A pound mol or molecular weight of any gas expressed in pounds occupies 359 ft<sup>3</sup> at 32°F and 29.92 in. of Hg or 379.4 ft<sup>3</sup> at 60°F and 14.7 psi.

tuyeres. The exact mechanism of gasification is not known, but it seems more logical to assume that gas-solid reactions are more likely to occur than those between two solids such as FeO and carbon. The effect of variations in the amount of C gasified above the tuyeres on the CO/CO<sub>2</sub> ratio will be considered later. For the immediate purpose of illustrating the method, it has been assumed that 208 lb or 17.33 mols of C reacts with CO<sub>2</sub>, a portion of which may be produced by the calcination of 8 mols or 800 lb of calcium carbonate.

By combining the results of the CO and CO<sub>2</sub> balances of Fig. 2, it is noted that the conversion of bosh gas to intermediate gas adds 5.36 mols of CO and 22.47 mols of CO<sub>2</sub> to the bosh gas. This increase of 27.83 mols, equivalent to 10,610 ft<sup>3</sup>, has diluted the N<sub>2</sub> from 64.0 to 58.0 pct. The percentage of CO in the intermediate gas is almost as high as in the bosh gas; 33.4 compared with 35. Due largely to the solution loss reaction, the gas contains but 7.8 pct CO<sub>2</sub> giving a CO/CO<sub>2</sub> ratio of 4.3. Thus if certain assumptions are made, some interesting observations may be made on the changes in the gas stream.

### Conversion of Intermediate Gas to Top Gas

The early step of reduction or the conversion of Fe<sub>2</sub>O<sub>3</sub> through Fe<sub>3</sub>O<sub>4</sub> to FeO takes place at much lower temperatures than the last step of reduction, i.e., the conversion of FeO to metallic iron. It seems permissible, therefore, to think of another major change in composition of the gas stream brought about by the reduction of Fe<sub>2</sub>O<sub>3</sub> to FeO in the upper part of the shaft by the reaction

The effect of this reaction, which involves no increase in volume but merely a conversion of CO to CO<sub>2</sub>, is readily determined as shown in Fig. 2.

The H<sub>2</sub> in the calculated top gas of Fig. 2 is low because the reaction

has not been considered. Some moisture from the charge is decomposed in the upper part of the furnace, but the reactions involved have not been established. Reaction 4 would reduce the CO/CO<sub>2</sub> ratio of 2.03 given for the top gas in Fig. 2 to 1.75 if 4 mols of hydrogen were so formed. The decomposition of water vapor by metallic iron would not alter this ratio. Until more information is available, the ratio given in Fig. 2 is tentative.

Knowing the blast moisture and the carbon used in solution loss and the composition of the top gas, one could determine the amount of H<sub>2</sub> formed in the upper part of the furnace. A comparison of actual CO/CO<sub>2</sub> ratios with calculated ratios based upon the formation of this H<sub>2</sub> by reaction 4 would shed some light on the mechanism of water decomposition in the upper shaft. Moisture added to the skip may react differently from water combined in the ore because the latter would come off at somewhat higher temperature. It is unlikely that moisture in the charge would persist low enough in the furnace in any case to change the intermediate gas.

### Solution Loss and Direct Reduction

Although the writer prefers to think of the gasification of C above the tuyeres as a gas-solid reaction, many prefer to associate this phenomena with the direct reduction of FeO by the reaction

A few calculations will show that the final results are stoichiometrically the same whether we consider the carbon is gasified by reacting with CO<sub>2</sub> gas or with solid FeO. Beginning with the same volume and composition of bosh gas as given in Fig. 2 and

Fig. 2—Detailed changes in composition of blast furnace gas.

considering the effect of gasifying 208 lb of C in direct reduction rather than with solution loss, the reactions for the conversion of bosh gas to intermediate gas are as follows:

The net result of these three reactions is a gain of 2.86 mols of CO and a gain of 14.47 mols of CO<sub>2</sub>. If 2.5 mols of CO from direct reduction is added, as was done in the CO balance of Fig. 2, the same total increase of 5.36 mols of CO is obtained. For CO<sub>2</sub> the gain is also the same as in Fig. 2, if 8 mols from the limestone is added. According to this mechanism, the conclusion would be that 17.33 mols of FeO out of 33.05, or about 56 pct of the iron, is reduced directly with solid C and 44 pct with H<sub>2</sub> and CO. To the writer the implications of such a division of reduction is not as meaningful as the statement that 208 lb of C are gasified with CO<sub>2</sub> with a loss of 5,830 Btu per lb of C. However, the method described can be used to study the process regardless of the preferred mechanism for reduction.

The gasification of carbon by oxygen from the charge is presumably more detrimental if it occurs at lower levels in the furnace. Unfortunately top-gas analyses or the calculations under discussion do not show where solution loss or direct reduction occur. They merely show the amount of C involved, the thermal effect and the effect on the volume and composition of the gas stream. Obviously carbon deposition cannot be isolated by the use of top-gas analyses.

### Solution Loss and Reducing Power of Gas Stream

The amount of C consumed at the tuyeres to satisfy the heat requirements, the amount of  $\text{CO}_2$  from the limestone, and the moisture in the blast all have a bearing upon the  $\text{CO}/\text{CO}_2$  ratio in the region of the mantle. Solution loss has a very pronounced effect upon this ratio because it involves the conversion of 1 mol of  $\text{CO}_2$  into 2 mols of CO. By calculations similar to those in Fig. 2 the effect of each of these factors can be studied.

Intermediate gas compositions were calculated for amounts of solution loss ranging from 0 to 300 lb and for amounts of carbon consumed at the tuyeres

Fig. 3—Equilibrium and calculated carbon gas ratios in the intermediate gas.

ranging from 1000 to 1600 lb. This range of carbon burned at the tuyeres would be equivalent to from 1400 to 2300 lb of coke charged per ton of iron. In making these calculations the volume of  $\text{CO}_2$  from the flux and the effect of moisture in the blast were held constant. The results of these calculations showing the effect of carbon burned at the tuyeres and solution loss on the  $\text{CO}/\text{CO}_2$  ratio in the intermediate gas are shown as generalized curves in Fig. 3. Equilibrium ratios of the carbon gases in contact with  $\text{FeO}$  at temperatures of 1472°, 1832°, and 2192°F have also been plotted in this figure to show the conditions under which these ratios are exceeded and reduction can occur. Equilibrium ratios for other temperatures, taken from Austin and Day,<sup>2</sup> are given in Table II.

It seems evident from Fig. 3 that when the solution loss exceeds 208 lb, the intermediate gas will be reducing towards ferrous oxide. Consider, for example, the case when 1200 lb of C is consumed at the tuyeres. The consumption of 208 lb of C by solution loss, 30 lb by reduction of metalloids, and 80 lb by solution in the iron, would mean that 1518 lb of C or about 1700 lb of coke are charged per ton

Table II. Equilibrium Ratios of Carbon Gases in Contact with  $\text{FeO}$

| Temperature |       | Ratio<br>$\text{CO}/\text{CO}_2$ | Temperature |       | Ratio<br>$\text{CO}/\text{CO}_2$ |
|-------------|-------|----------------------------------|-------------|-------|----------------------------------|

| 1,292       | 700   | 1.53                             | 2,192       | 1,200 | 3.21                             |
| 1,472       | 800   | 1.90                             | 2,372       | 1,300 | 3.47                             |

of iron. Under these conditions, the  $\text{CO}/\text{CO}_2$  ratio of the intermediate gas is equal to 4.75 compared with an equilibrium ratio of 1.9 at 1472°F (800°C).

For an overall appraisal of the situation it appears that a  $\text{CO}/\text{CO}_2$  ratio of 3 or higher should be maintained. Such a ratio would require that a minimum of 1200 lb of C be burned at the tuyeres if 108 lb of C be consumed in solution loss, see Fig. 3. Gruner's ideal furnace would require the consumption of over 1700 lb of C at the tuyeres, equivalent to over 2000 lb of coke charged, to obtain a  $\text{CO}/\text{CO}_2$  ratio of 3 in the intermediate gas. Thus it may be seen that only when large amounts of fuel are needed to satisfy fuel requirements can furnaces operate without solution loss. It appears that a solution loss of some 200 lb, which is typical of Lake ore practice, may be reduced to about 100 lb without exhausting the reducing power of the intermediate gas. The combustion of an additional 100 lb of C at the tuyeres rather than the gasification of an equal amount above the tuyeres would increase the heat made available to the process by about 1,000,000 Btu. The fact that about 200 lb of C is consumed above the tuyeres merely means that operations are not on properly sized and easily reduced ore burdens.

Assuming that 108 lb, or 9 mols, of C must be gasified above the tuyeres to maintain the reducing power of the gas, it follows that 9 mols of  $\text{FeO}$  must be reduced directly with solid carbon. This would correspond with about 27 pct of the 33.05 mols of  $\text{FeO}$  needed to produce the metallic iron in a net ton of pig iron. For those who prefer to think in terms of the solid carbon or direct reduction reaction, it appears, therefore, that some 25 pct of direct reduction is necessary in typical Lake ore practice to maintain the reducing power of the bosh gas.

### Effect of Countercurrent Flow

Under the conditions of countercurrent flow of the blast furnace, the descending ore burden comes in contact with ascending gas progressively higher in CO and progressively hotter. This offers distinct advantages because the charge richest in  $\text{FeO}$  comes in contact with gas at the lowest temperature and with the lowest  $\text{CO}/\text{CO}_2$  ratio. On the other hand, the charge containing very little  $\text{FeO}$  in the final

stages of reduction comes in contact with bosh gas containing little, if any, CO<sub>2</sub>.

Calcination of the limestone and the reaction of CO<sub>2</sub> with C begin very slowly at about 1400° and increase rapidly with temperature above 1800°F. In preparing Fig. 4 it has been assumed for the sake of simplicity that reduction, calcination, and solution loss take place in 10 equal steps as the charge moves through a temperature range of 1400° to 2400°F. As indicated, bosh gas containing no CO<sub>2</sub>

Fig. 4—Steps in the conversion of bosh gas to intermediate gas.

enters zone 10, in which the last 10 pct of FeO is reduced to metallic iron. Moving through the successive zones, the gas stream acquires oxygen from the charge and finally emerges as intermediate gas having acquired the oxygen associated with the first stages of reduction of FeO and the first stages of calcination. As shown in Fig. 3, this gas has a definite composition under fixed conditions of fuel consumption, blast moisture, limestone requirements, and solution loss.

#### Calculated and Equilibrium Ratios of Carbon Gases

As shown in Table II, higher CO/CO<sub>2</sub> ratios must be maintained to facilitate reduction at higher temperatures. For example, the equilibrium ratio increases from 1.9 at 1400°F to 3.5 at 2400°F. Fortunately, the gas is very rich in CO at the highest temperature, as indicated by the calculated CO/CO<sub>2</sub> ratios given in Fig. 5. It appears that the closest approach to equilibrium occurs in the early stages of FeO reduction and in the early stages of calcination. In this cooler part of the shaft the equilibrium ratios are somewhat less than 2 whereas the calculated ratio at the lowest temperature indicates a value of 3 for the CO/CO<sub>2</sub> ratio. When 1200 lb of C are burned at the tuyeres, a solution loss of 108 lb will, it appears, maintain reducing conditions in the gas stream. If conditions of higher fuel consumption or higher solution loss were assumed, a series of generalized curves similar in shape to the upper one in Fig. 5, but at higher positions, would be obtained.

#### Nitrogen in Top Gas as Key to Solution Loss

In as much as the N<sub>2</sub> of the blast is relatively inert and passes through the furnace without reaction, it can be very useful as a measure of solution loss or direct reduction.

Brief reference to Fig. 2 will show how and to

what extent a change in solution loss alters the volume of the gas and in turn the degree of the dilution of nitrogen. Each pound mol of C that reacts with CO<sub>2</sub>

increases the volume of the gas stream by 1 mol. A mol of CO<sub>2</sub> is consumed, but 2 mols of CO are formed by reaction 9.

If in place of the 208 lb of solution loss, considered in Fig. 2, only 100 lb of C is gasified, the gas volume will be reduced by 9 mols. That is the 286.27 mols of intermediate gas and top gas will be reduced to 277.27 mols. The constant volume of 165.44 mols of N<sub>2</sub> is now equal to 59.7 pct of the total volume; an increase of 1.7 pct over the value of 58.0 pct reported in Fig. 2. Thus, a decrease of 108 lb in solution loss results in an increase of 1.7 pct in the N<sub>2</sub> content of the intermediate and in the top gas. For a fixed coke rate high N<sub>2</sub> means low solution loss.

In a given practice the CO<sub>2</sub> from the stone and the moisture in the blast will remain fairly constant but their effects on N<sub>2</sub> dilution are appreciable. For example, an increase of 200 lb of CaCO<sub>3</sub> or 2 mols would increase the gas volume to 288.27 mols, thus reducing the N<sub>2</sub> from 58.0 to about 57.5 pct. Similarly, each mol of C consumed in the water gas reaction

adds 2 mols of gas without contributing any nitrogen. Thus one additional mol of C consumed at the tuyeres with moisture in the blast and 2 additional mols of CaCO<sub>3</sub> in the limestone dilute the N<sub>2</sub> to about

Fig. 5—Calculated and equilibrium carbon gas ratios at various temperatures.

the same degree. The specific affects of solution loss, CO<sub>2</sub> from the stone and moisture in the blast will be considered in greater detail later.

Fuel consumption also has a bearing upon the dilution of nitrogen. High fuel requirements normally mean more air and more N<sub>2</sub> per ton of pig. The combined action of solution loss, calcination, and direct reduction in diluting the N<sub>2</sub> will generally be less when the fuel consumption is high. In other words, a high N<sub>2</sub> content of the top gas is normally

Fig. 6—Fuel consumption solution loss and the nitrogen content of top gas.

associated with high fuel consumption. Sufficient progress has been made in equipment to get continuous records of top-gas composition to warrant further study of the significance of such data as an index of furnace reactions.

A generalized picture of the effect of solution loss upon the  $N_2$  content of the top gas is given in Fig. 6. Following the methods previously described, the composition of the top gas was calculated for zero up to 300 lb of solution loss and for 1000 to 1500 lb of C at the tuyeres per ton of pig iron. If the fuel consumption is high, the nitrogen in the blast required to consume this large amount of carbon suffers less dilution by  $CO_2$  from the limestone, by the solution loss reaction and by the direct reduction of metalloids. With a constant solution loss of 200 lb

Fig. 7—Moisture in the blast and nitrogen in the top gas.

the top gas will, according to Fig. 6, contain about 60 and 57.6 pct  $N_2$ , respectively, when 1500 and 1000 lb of C are burned at the tuyeres.

When fuel requirements are fairly fixed as indicated by each of the six curves, the  $N_2$  in the top gas becomes an index of solution loss. For example if the heat requirements are such as to demand about 1100 lb of C at the tuyeres, the  $N_2$  in the top gas will drop from 59.9 to 58.2 pct if the solution loss increases from 100 to 200 lb per ton of iron. Such changes in  $N_2$  are readily detected so that with properly prepared curves to compensate for moisture in the blast and  $CO_2$  from the stone, top-gas analyses afford a direct means of following solution loss.

In order to observe the dilution of  $N_2$  in the top gas by blast moisture, calculations were made for three levels of moisture in the blast; dry blast, 3.82 and 7.64 grains-ft<sup>3</sup>. With these respective amounts of moisture in the blast, zero, 30 and 60 lb of C would be consumed per ton of iron. This assumes a constant volume of 82,500 ft<sup>3</sup> of dry air, capable of burning 1100 lb of C at the tuyeres per ton of iron

$$\left( \frac{4.76 \times 379.4}{24} = 75 \text{ ft}^3 \text{ air per lb of C} \right).$$

The action of moisture in the blast as a  $N_2$  diluent is summarized in Fig. 7 for a wide range of solution loss. An increase of 3.82 grains of blast moisture lowers the  $N_2$  in the top gas by about 1 pct. It does so of course because this amount of moisture will consume 2.5 mols of C and produce 5 mols or 1897 cu ft of  $H_2$  plus  $CO$ .

Except for the endothermic effect of the water gas reaction it represents a form of oxygen enrichment. A pound mol of water vapor will gasify a pound mol of C whereas it requires 2.38 mols of air per mol of C, see Fig. 1. Thus the combustion potential of 1 ft<sup>3</sup> of water vapor is equivalent to 2.38 ft<sup>3</sup> of dry air. On the gas produced side, it is of interest to note that 2 mols of  $H_2$  plus  $CO$  are produced per mol of C consumed with  $H_2O$  whereas 2.88 mols of  $CO$  and  $N_2$  are produced per mol of C gasified with dry air. In other words, high moisture favors a more rapid rate of driving because of the greater combustion potential of moisture and also because less gas is produced per pound of C gasified.

### Effect of Limestone on Nitrogen in Top Gas

The effect of  $CO_2$  from the stone as shown in Fig. 8 can be seen very readily if it is remembered that each additional 100 lb of flux represents about 100 lb, or 1 mol, of  $CaCO_3$  equivalent to 1 mol of  $CO_2$ . An increase from 800 to 1100 lb of flux means, therefore, an addition of about 3 mols of  $CO_2$  or roughly 1.0 pct of the 286.27 mols shown in Fig. 2. Since the gas contains about 58.0 pct  $N_2$  such a percentage reduction would be a reduction of about 0.6 pct  $N_2$ . Such a reduction in  $N_2$  can be observed for each of the three levels of carbon consumption in Fig. 8. In general, the effects of changes in the amount of flux used will be masked by the effect of solution loss or blast moisture. However, adjustments must be made for variations in the flux to isolate the effect of solution loss.

Since the details of calculations for dealing with furnace problems in pound mols have been given in the hope that it may be of value in studying the smelting process, it may be permissible to show how the method assists in following other changes as well as changes in solution loss. Suppose, for example,

that 900 lb of high-combined moisture material were substituted for 900 of a low-combined moisture material such as sinter. An increase of 10 pct in combined moisture would represent 90 lb, or 5 mols, of water vapor. This would be equivalent to an increase of about 1.75 pct in the volume of the gas liberated in the upper part of the shaft and may necessitate a slower rate of operation in the case of a furnace already blown near the maximum rate.

### Solution Loss and Volume of Gas Generated

Since 1938, the demand for steel and pig iron has been conducive to operation of blast furnaces at maximum rates consistent with efficiency and the production of flue dust. Under these conditions, the linear velocity of the gas through the stock imposes the final limitation on the amount of wind that can be blown in a given furnace. Although solution loss or the oxidation of carbon above the tuyeres by oxygen in the charge reduces the volume of gas generated per pound of carbon gasified in the furnace as a whole, the use of high-top pressure, described in a number of reports,<sup>3-5</sup> is a more effective

transfer. It is conceivable, therefore, that a decrease in solution loss may result in a temporary loss of tonnage. Actually, a decrease of 108 lb of solution loss would increase the heat available to the process by about 1,000,000 Btu. It seems more likely that such an increase in available heat would result in some increase in hearth temperature which would in turn permit a reduction in fuel, in air, and in the gas produced to the end that there would be a reduction in fuel required but not in tonnage. A high-solution loss of carbon does not appear to be a proper way to reduce gas velocities in the furnace shaft. Size preparation of the ore or high-top pressures would appear to be more promising methods of reducing the linear velocity of the gas through the stock.

### Summary and Conclusions

Further study of the gas phase of the blast furnace process offers a means of learning more about the process. Simple calculations based upon the use of the pound mol to make a material balance indicate that the consumption of about 100 lb of C in solution loss or by direct reduction of FeO will maintain a reducing gas in the region of the mantle in typical Lake ore practice. Few data are available but it appears that about 200 lb of C normally is consumed above the tuyeres. More reducible burdens and burdens better prepared physically will be necessary to make an additional million Btu available to the process by a reduction of 100 lb in the C gasified above the tuyeres.

An increase in solution loss temporarily increases the rate of furnace driving for a constant rate of blowing merely because more carbon is gasified with oxygen from the charge. However, since the heat available is reduced, more fuel eventually must be used so that in the end solution loss in excess of about 100 lb means a loss of both tonnage and efficiency. With better prepared burdens physically or with higher top pressures, the additional gas produced by burning more carbon at the tuyeres should not present a problem.

The generalized curves illustrate what can be done with calculations similar to those outlined in the paper. They are not intended for general use but as a guide for similar curves made to fit a particular practice. It is to be hoped that continuous top-gas analysis will be used in interpreting what is going on in the furnace to the end that more will be learned about the basic features of the smelting process. All will agree that a better understanding of the process is needed to appraise the value of new raw materials as well as innovations in practice such as high-top pressures, beneficiated ore burdens, and oxygen enriched blast.

Fig. 8—Flux requirements and nitrogen in the top gas.

way of reducing linear gas velocities without disturbing the thermal balance of the operation.

In the calculations of Fig. 2, 208 lb of C are consumed above the tuyeres and 1056 at the tuyeres with dry air. It may be assumed that a more easily reduced burden, better gas distribution, and smaller limestone reduce solution loss by 108 lb, or 9 mols, of C. Under these conditions the 9 additional mols of C to be consumed at the tuyeres per ton of pig iron would require 21.42 additional mols of air and 25.92 additional mols of bosh gas would be produced per ton of pig iron.

$$\left( 9 \times \frac{4.76}{2} = 21.42; 9 \times \frac{5.76}{2} = 25.92 \right)$$

This may be compared with the combustion reaction, Fig. 1. This increase in the volume of bosh gas would be partly offset by a reduction of 9 mols in the gas produced by solution loss.

The net effect of more bosh gas and a reduction in the volume of CO from solution loss would be the addition of 16.92 mols of intermediate gas per ton of pig. On the basis of 286.27 mols of intermediate gas, this is equivalent to an increase of 5.9 pct in the volume of the gas per ton of iron.

Such an increase in the gas to be forced through the charge may, in the case of a furnace operating near critical gas velocities, lead to channelling, an increase in dust production, and less favorable heat

# Metallographic Study of the Martensite Transformation in Lithium

by J. S. Bowles

THE martensite transformation in lithium, discovered by Barrett,<sup>1</sup> has been studied extensively by X-ray techniques by Barrett and Trautz,<sup>2</sup> and Barrett and Clifton.<sup>3</sup> The present paper reports the results of an investigation into the metallographic characteristics of lithium martensite. Such an investigation has not been carried out before.

The spontaneous transformation in lithium consists of a change from a body-centered cubic to a close-packed hexagonal structure with the hexagonal layers in imperfect stacking sequence.<sup>4</sup> As far as is known at present, this transformation can be regarded as being crystallographically equivalent to the body-centered cubic to close-packed hexagonal transformation that occurs in zirconium,<sup>5</sup> although stacking errors have not been reported in zirconium.

From a study of the orientation relationships in zirconium, Burgers<sup>5</sup> has proposed that the martensite transformation, b.c.c. to c.p.h., occurs by a heterogeneous shear on the system (112)  $[11\bar{1}]$ . The crystallographic principle underlying this proposal is that the configuration of atoms in the (112) plane of a b.c.c. structure is exactly the same as that in the (10 $\bar{1}0$ ) plane of a close-packed hexagonal structure based on the same atomic radius. The pattern in

both these planes is a rectangle  $d \times \frac{2\sqrt{2}}{\sqrt{3}} d$  where

$d$  is the atomic diameter. Thus a close-packed hexagonal structure can be built up from a body-centered cubic structure by displacing the (112) planes relative to each other.\* This mechanism leads to orientations that can be described by the relations:

$$(110)_{b.c.c.} // (0001)_{c.p.h.}; [\bar{1}11]_{b.c.c.} // [11\bar{2}0]_{c.p.h.}$$

Observations confirm these relations. In zirconium, Burgers' measurements indicated an angle of 0° to 2° between the close-packed directions, while Barrett's measurements on lithium indicated an angle of 3°.

According to the Burgers' mechanism, the martensite habit plane for this transformation would be expected to be the (112)<sub>b.c.c.</sub> plane, for this plane would not be distorted by the transformation. One of the purposes of this investigation was to find out whether the observed lithium habit plane agrees with this prediction of the Burgers' mechanism.

## Experimental Procedure

**Materials:** The lithium was from the same purified ingot used by Barrett and Trautz.<sup>2</sup> The Bridgman technique was used to produce single crystals. To maintain a temperature gradient in the melt, during the production of these crystals, it was necessary to use a steel mould with a wall thickness of only 0.015 in.

**Metallographic Techniques:** Lithium specimens could be given an excellent metallographic polish by swabbing them gently with cold methyl or ethyl alcohol.† The best results were obtained with methyl alcohol saturated with the reaction product, lithium alcoholate. With higher alcohols the reaction became progressively slower and the attack became an etch pit attack rather than a polish attack. Butyl and amyl alcohols were used for macroetching.

After polishing, it was necessary to remove all traces of alcohol from the specimens; otherwise, on subsequent quenching in liquid nitrogen, the alcohol froze to a glassy film. The alcohol was removed with dry benzene. The benzene in turn had to be removed before quenching, but since it does not react with lithium it could be allowed to evaporate. The specimens could then be quickly quenched before they began to tarnish. This operation could be carried out in air on all but excessively humid days when it was advisable to use an atmosphere of dry nitrogen or argon. For examinations at room temperature, the specimens could be transferred directly from the benzene bath into a bath of mineral oil. In mineral oil the specimens oxidized slowly by the diffusion of oxygen through the oil but the structure remained visible for about an hour.

**Lithium Martensite:** Specimens prepared in the manner described above transformed spontaneously to martensite with an audible click when quenched into liquid nitrogen; i.e.,  $M_s$  was above the boiling point of nitrogen (77°K). The disparity between this result and the  $M_s$  temperature of 71°K, found by Barrett and Trautz, is probably to be attributed to the large grain size and freedom from mechanical deformation of the specimens used in the present work.

The relief effects produced by the transformation did not disappear when specimens were quenched from liquid nitrogen into mineral oil at room temperature. This permitted the microstructures to be studied at room temperature where, of course, the martensitic phase was no longer present. Typical micrographs of lithium "martensite" made at room temperature are reproduced in figs. 1, 2, and 3. As anticipated by Barrett and Trautz, the microstruc-

\* It should be noted that the array on the (110)<sub>b.c.c.</sub> plane cannot be converted into an exact hexagonal array by the simple shear proposed by Burgers, since the spacings of the (112)<sub>b.c.c.</sub> and (10 $\bar{1}0$ )<sub>c.p.h.</sub> planes are not exactly equal. A contraction would have to be superimposed on the proposed shear.

† Sodium can also be polished metallographically in this way, using propyl alcohol instead of methyl alcohol.

J. S. BOWLES, formerly associated with the Institute for the Study of Metals, University of Chicago, is now with the Division of Tribophysics, Commonwealth Scientific and Industrial Research Organization, University of Melbourne, Carlton, Vic., Australia.

Discussion of this paper, TP 2977 E, may be sent (2 copies) to AIME by April 1, 1951. Manuscript, Aug. 2, 1950; St. Louis Meeting, February 1951.

Fig. 1 (upper left)—Lithium martensite relief effects photographed at room temperature. X100.

Fig. 2 (upper right)—Lithium martensite relief effects photographed at room temperature. X150.

Fig. 3 (lower left)—Lithium martensite relief effects photographed at room temperature. X200.

tural characteristics of lithium martensite were essentially similar to those of other martensitic phases. The relief effects produced by the transformation consisted essentially of a simple tilting of the surface about its intersection with the habit plane. This type of relief appeared to be typical of martensite transformations. The lithium martensite plates also frequently showed a set of transverse markings. As in other systems, the transformation at  $M_s$  appeared to be a highly cooperative affair, for a whole network of plates suddenly appeared. Apparently many plates, both in the same crystal and in neighboring crystals, were triggered off by the formation of the first plate. The zig-zag linkage, which is so predominant a feature of other martensitic structures, also occurred very frequently.

When a specimen was covered with a frozen film of alcohol, martensite relief effects were not produced on the surface on quenching into liquid nitrogen, i.e., these films appeared to suppress the transformation. These films were quite transparent, and although they had the form of a cracked mosaic, the microstructure of the underlying lithium could be seen quite clearly. Many specimens coated with alcohol films were cooled to the melting point of nitrogen ( $63^\circ\text{K}$ ), i.e., more than  $14^\circ$  below  $M_s$  and no relief effects were ever observed. Films of frozen propane caused the same behavior. X-ray diffraction experiments were carried out at liquid nitrogen temperature to see whether the films completely inhibited transformation. In general diffraction lines of the martensite phase were detected in these specimens. There appear to be two possible interpretations of these results. The films may have inhibited transformation at the surface but not in the interior, or the films may not have been continuous on the backs and edges of the specimen that could not be polished properly, and transformation may have occurred there.

**The Habit Plane:** The persistence of the relief effects on quenching from liquid nitrogen into mineral oil at room temperature greatly facilitated the determination of the lithium habit plane, for it meant

that trace measurements could be made at room temperature. Orientations were determined by the back-reflection method using a precision camera designed to permit Laue patterns to be taken at previously selected positions on the specimen. To prevent the diffraction pattern of the base from appearing in the photograph, a plug of litharge-glycerin cement was inserted in the aluminum specimen holder. Crystals that passed completely through the specimen were selected to prevent the Laue patterns of underlying crystals, as well as of the crystal under investigation, from appearing on the film.

The method of determining the habit plane from the observed traces consisted of plotting the zone that was normal to each trace in a single stereographic triangle and determining the common point of intersection of all the zones. In this way an unambiguous solution for the habit plane could be obtained without making measurements of the traces of any single plate on more than one surface. The procedure is illustrated in fig. 4. Fourteen trace normals in four different crystals all passed within  $\pm 1\frac{1}{2}^\circ$  of the solution indicated in fig. 4. This plane, which is  $10\frac{1}{2}^\circ$  from (110) can be described approximately by the indexes  $\{441\}_{h.c.c.}$ .

### Discussion of Results

The result obtained for the lithium habit plane is of interest for several reasons. First, it is now clear that the observed habit plane is not that predicted by the Burgers' mechanism and that this mechanism will therefore have to be revised. Second, the observed habit plane is closely similar to the habit

Fig. 4—Stereographic projection of the pole of the lithium martensite habit plane illustrating the method of determining the habit plane from trace measurements on single surfaces.

planes utilized in a number of other martensite transformations in body-centered cubic metals (table I). It seems reasonable to conclude from this recurrence of nearly the same habit plane for essentially equivalent transformations in quite different systems, that the choice of habit plane is determined by the geometry of the transformation mechanism rather than by other considerations.

The relief effects produced by the transformation consisted essentially of a simple tilting of the surface about its intersection with the habit plane. This means that the transformation involves a homogeneous distortion of the original structure, in which the habit plane is a plane of zero distortion. However, since the body-centered cubic structure is a space lattice with a single atom motif, it will remain

**Table I. Habit Planes in Martensite Transformations**

| System | Transformation                                                  | Habit Plane |
|--------|-----------------------------------------------------------------|-------------|
| Cu-Al  | b.c.c. $\rightarrow$ Distorted c.p.h. ( $\beta'$ ) <sup>9</sup> | (441)       |
| Cu-Al  | b.c.c. $\rightarrow$ c.p.h. ( $\gamma'$ ) <sup>9</sup>          | (221)       |
| Cu-Zn  | b.c.c. $\rightarrow$ f.c.t. (?) <sup>10</sup>                   | (551)       |
| Cu-Sn  | b.c.c. $\rightarrow$ Structure unknown <sup>10</sup>            | (331)       |
| Au-Cd  | b.c.c. $\rightarrow$ Orthorhombic <sup>11</sup>                 | (331)       |
| Li     | b.c.c. $\rightarrow$ c.p.h.                                     | (441)       |

a space lattice with a single atom motif throughout any succession of homogeneous distortions. Clearly then, the observed change in structure cannot be achieved by the observed homogeneous distortion. Additional atom movements that do not cause any observable change in shape of the plate must also occur. The transformation b.c.c.  $\rightarrow$  c.p.h. therefore involves two distortions of the original lattice, one homogeneous and the other heterogeneous. In this respect it is analogous to the f.c.c.  $\rightarrow$  b.c.t. transformation that occurs in Fe-C alloys<sup>6</sup> and the f.c.c.  $\rightarrow$  f.c.t. transformation that occurs in In-Tl alloys.<sup>7</sup>

Recent studies of these transformations have demonstrated clearly the nature of the problems involved in the determination of the crystallographic mechanisms of martensite transformations. It is necessary to decide first, what net atom displacements are needed to build up a unit cell of the new phase, and second, how this "unit distortion" is repeated throughout the parent lattice. The criterion of an acceptable mechanism is, of course, that it be consistent with all the geometrical features of the transformation, e.g., orientation relationships, habit plane, etc.

In the Fe-C and In-Tl transformations, the net atom displacements that occur are those that lead to the smallest overall distortion of the parent lattice. That this is also true for at least one of the b.c.c.  $\rightarrow$  c.p.h. transformations is indicated by the work of Kurdjumow and Miretsky<sup>8</sup> who have shown that the assumption of minimum overall distortion leads to a prediction of the observed superlattice in Cu-Al martensite. Since these minimum displacements are exactly those proposed by Burgers, it seems very likely that the Burgers' mechanism is correct as far as the displacements in any small region are concerned.

If this conclusion is correct, then to modify the Burgers' mechanism so that it becomes consistent with the observed habit plane and relief effects necessitates a consideration of the manner in which this unit distortion is repeated throughout the lattice.

In the Fe-C and In-Tl transformations, the unit distortion is not repeated as a simple homogeneous

distortion throughout the lattice. It is necessary to describe the correspondence between atom positions before and after transformation by two distortions, the first homogeneous and the second heterogeneous. The homogeneous component accounts satisfactorily for the observed habit plane and relief effects, and in the indium-thallium alloys for the observed propagation of the transformation distortions at an interface parallel to the habit plane. The heterogeneous component is necessary to complete the transformation, and accounts for the transverse markings that are seen in martensite plates. The problem of explaining the observed habit plane and relief effects in the b.c.c.  $\rightarrow$  c.p.h. transformation probably has an analogous solution, but a geometrical analysis of the distortion indicated by the relief effects will be needed before a complete description of the transformation mechanism can be given. Since lithium is not a suitable material for such work, it will probably be simpler to carry out such an analysis for one of the other systems.

### Summary

1. Techniques have been developed for the metallographic examination of lithium and the microstructural characteristics of lithium martensite are described.

2. The lithium habit plane has been shown to be approximately {441}. This is not in agreement with Burgers' prediction of {112} but is closely similar to the habit planes utilized in other martensite transformations in body-centered cubic metals.

3. The atom movements proposed by Burgers are probably correct for they are consistent with the observed superlattice in Cu-Al martensite. To modify Burgers' mechanism so that it becomes consistent with the observed habit plane and relief effects, it will be necessary to find out how the "Burgers' unit distortion" is repeated throughout the lattice.

### Acknowledgment

The author is indebted to the Commonwealth Scientific and Industrial Research Organization, Australia, and to the University of Chicago for research studentships.

He wishes to acknowledge gratefully the assistance he received from W. Bergmann and John Barrett in preparing the lithium single crystals. He also wishes to thank C. S. Barrett, L. Guttman and J. B. Hess for many valuable discussions.

# Plastic Deformation and Diffusionless Phase Changes In Metals — The Gold-Cadmium Beta Phase

by L. C. Chang and T. A. Read

Diffusionless transformation in Au-Cd single crystals containing about 50 atomic pct Cd was investigated by means of X-ray analysis of the orientation relationships, electrical resistivity measurements, and motion picture studies of the movement of boundaries between the new and old phases during transformation. The nucleation of diffusionless transformation by imperfections and the generation of imperfections by diffusionless transformation were discussed.

THAT connections exist between plastic deformation and diffusionless phase changes has long been recognized. Thus it is often possible to produce a diffusionless phase change in a temperature range, above that in which the change occurs spontaneously, by cold-working the initial phase.

Certain aspects of the dislocation theory of the plastic deformation of crystalline solids also provide for a rather direct connection between the processes involved in plastic deformation and in diffusionless phase changes. Heidenreich and Shockley<sup>1</sup> have pointed out that simple edge dislocations in f.c.c. metals are probably unstable, and that the more probable lattice imperfections, called extended edge dislocations, consist of two half dislocations separated by a distance of the order of magnitude of 100Å. The region about two atomic planes thick between the half dislocations because of this stacking fault may be described as having the hexagonal close-packed structure. Presumably the stacking faults observed by Barrett<sup>2</sup> after cold-working f.c.c. Cu-Si alloys resulted from the passage of such half dislocations through the lattice of the initial phase.

It is now becoming clear that the development of a detailed theory of the atomic movements involved in diffusionless phase changes will require a consideration of the role played by lattice imperfections, just as such considerations are necessary to the understanding of plastic deformation mechanisms. This point of view has been recently set forth, for example, by Cohen, Machlin, and Paranjpe<sup>3</sup> who pointed out the role which might be played by screw dislocations in nucleating diffusionless phase changes.

The present paper reports on some aspects of the diffusionless phase change in single crystals of the beta phase alloy Au-Cd which serve to emphasize further the importance of lattice imperfections in diffusionless phase changes.

The diffusionless phase change of Au-Cd possesses

several remarkable features. One of these is that the interface between the high-temperature beta phase and the low-temperature orthorhombic phase typically moves with a low velocity, in contrast to the behavior observed in the transformation of austenite to martensite. Motion pictures of this slow interface motion have been prepared in the course of the work reported here.

Another important feature of the Au-Cd transformation is the small amount of undercooling observed. The reverse transformation occurs on reheating to a temperature only 20° higher than the transformation temperature observed on cooling, and under some circumstances the hysteresis observed is substantially less than this. This narrow temperature range between transformation on heating and cooling is presumably in part a consequence of the fact that the transformation requires a lattice shear of only about 3°.

Finally, the orthorhombic product phase possesses unusual mechanical properties, as was first pointed out by Ölander<sup>4</sup> and Benedicks.<sup>5</sup> After completion of the transformation on cooling the specimen can be severely deformed, yet on the release of load it springs back to its original shape in a rubber-like manner. Explanation of this phenomenon will require an understanding of the lattice imperfections in the orthorhombic structure and, correspondingly, of those in the initial body-centered cubic structure.

Single crystals of Au-Cd alloy containing 47.5 and 49.0 atomic pct Cd were prepared from fine gold (99.95 pct purity) and chemically pure cadmium (99.99 pct purity) by melting the alloy in an evacuated and sealed fused quartz tubing and growing into single-crystal form by the Bridgman method. The Au-Cd alloy containing 47.5 atomic pct Cd undergoes a diffusionless transformation from an ordered body-centered cubic structure to an orthorhombic structure when it is cooled to about 60°C, while the reverse transformation takes place when the alloy is heated to about 80°C, according to electrical resistivity studies. The structures of these two phases have been studied by Ölander,<sup>4</sup> reinvestigated by Bystrom and Almin.<sup>6</sup> The lines of Debye photograph of powdered samples of Au-Cd alloy containing 47.5 atomic pct Cd prepared in this laboratory were identified and agreed fairly well with those of

L. C. CHANG and T. A. READ, Members AIME, are Member of the Scientific Staff and Associate Professor of Metallurgy, respectively, in the School of Mines, Columbia University, New York.

Discussion on this paper, TP 2941 E, may be sent (2 copies) to AIME by April 1, 1951. Manuscript, June 19, 1950; revision Nov. 16, 1950; St. Louis Meeting, February 1951.

Ölander. The crystal structures of the two phases are as follows:<sup>12</sup>

High-temperature phase ( $\beta_1$ ):

CsCl structure, 2 atoms per unit cell, ordered.  
 $a = 3.3165 \pm 0.0005$  kX units.

Low-temperature phase ( $\beta'$ ):

Orthorhombic,  $a = 3.1476$ ,  $b = 4.7549$ ,  $c = 4.8546$ ,  $\pm 0.0005$  kX units.

Two Cd atoms approximately located at 0,0,0  
 $0, \frac{1}{2}, \frac{5}{8}$

Two Au atoms approximately located at  $\frac{1}{2}, 0, \frac{1}{2}$   
 $\frac{1}{2}, \frac{1}{2}, \frac{1}{8}$ .

The Au-Cd alloy containing 49.0 atomic pct Cd undergoes a diffusionless transformation from the ordered body-centered cubic structure to a tetragonal structure<sup>7</sup> when it is cooled to about 30°C; and the reverse transformation typically takes place when the alloy is heated to about 40° to 55°C, depending on the previous history of the alloy. The structural details of the tetragonal phase are not known.

### Experimental Procedure

The back-reflection Laue method was used to determine the orientations of the single crystal  $\beta_1$  phase. The specimen was fixed in a holder provided with means of heating and cooling the specimen without disturbing its position. By this means the orientation relationship between the  $\beta_1$  and  $\beta'$  phases was determined. The transformation markings and the plane of moving interface between the  $\beta_1$  and  $\beta'$  phases during transformation were determined by measuring the traces of the markings across two flat surfaces perpendicular to each other.

The change in resistivity of the Au-Cd single crystals on cooling and heating through the transformation temperature range with and without applied stress was studied. The measurements were obtained by setting the sample in a wedge against two knife edges. A current of about 5 amp was sent through the sample and the voltage drop between the knife edges was measured by a Leeds and Northrup K-2 potentiometer. The current going through the sample was measured by placing a calibrated shunt in series in the circuit and measuring the voltage drop across the shunt with another K-2 potentiometer.

The orthorhombic  $\beta'$  phase possesses a characteristic pseudo-rubberlike behavior. The stress-strain curves of this phase within the quasi-elastic range were also obtained.

Motion pictures, taken at a magnification of 100 diam, were prepared which reveal the changes in surface contour of a metallographically polished single-crystal specimen containing 47.5 atomic pct Cd. These changes in contour make it possible to follow the motion of the interface between the new and old phases, both on heating and on cooling.

### Results

**Orientation Relationships:** The orientation relationships between the  $\beta_1$  and  $\beta'$  phases of the Au-Cd single crystal containing 47.5 atomic pct Cd, from several independent determinations from back-reflection Laue patterns, were found as follows:

$(011)_{\beta_1}$  parallel to  $(001)_{\beta'}$  (planes)

$[\bar{1}\bar{1}1]_{\beta_1}$  parallel to  $[\bar{1}\bar{1}0]_{\beta'}$  (directions).

**Transformation Markings and Moving Interfaces:** In general, a single crystal of the cubic high-

temperature phase  $\beta_1$  does not transform on cooling to a single crystal of the low-temperature phase  $\beta'$ . Instead, the sample is found after transformation to consist of an aggregate of crystals of the low-temperature phase. The relative orientations of these crystals correspond to the various crystallographically equivalent transformation lattice shears. Thus, in general, the transformation of the single-crystal specimen as a whole is inhomogeneous. This is clearly shown by the fact that if a polished flat surface is prepared on the specimen while it is hot, and thus has the cubic structure, this surface is no longer plane after transformation to the orthorhombic structure. If the transformation occurred in a completely homogeneous way, the plane surface of the cubic crystal should remain plane and free of surface markings after transformation. These heterogeneous transformation strains are, however, completely reversed on reheating to the cubic phase. The strain markings disappear and the originally plane surface becomes plane again. In the following this will be referred to as a "multiple interface transformation."

In the present work success has been achieved in producing a transformation from the cubic to the orthorhombic phase by the motion of a single interface. In this case transformation starts at one end of the cubic single-crystal specimen, and then, on continued cooling, the interface between the two phases is translated toward the other end of the specimen. The shear character of the transformation is readily apparent from the appearance of the specimen after partial transformation; the flat surface on the original cubic crystal has become two plane surfaces which intersect in a sharp corner at the interface, and the dihedral angle agrees with that predicted from the lattice shear value from the X-ray diffraction observations. After complete transformation to the orthorhombic structure no strain markings are visible on the polished surface of the sample. This will be referred to here as a "single interface transformation."

The pre-treatment of the crystal sample required to achieve the homogeneous transformation described above includes an anneal of several days a few degrees below the solidus temperature.

The plane of the interface between the two phases during single interface transformation is the (331) of the cubic phase, within the experimental error of approximately 2°.

**Reversible Orientation Relationships:** During the determination of orientation relationships of the transformation, it was invariably found that when a single crystal of  $\beta_1$  transformed by the multiple interface mechanism into a crystal aggregate of  $\beta'$ , on reverse transformation a single crystal of the initial orientation was obtained. The same phenomenon was also observed in the Au-Cd single crystal containing 49.0 atomic pct Cd.

**Resistivity Measurements:** The change in electrical resistivity of the Au-Cd single crystal (containing 47.5 atomic pct Cd) on cooling and reheating through the transformation temperature range

Table I. Temperature of Beginning of Transformation

|              | Cooling, °C   |      | Heating, °C   |      |
|--------------|---------------|------|---------------|------|
|              | $M^{\circ}_s$ | 61.0 | $M^{\circ}_c$ | 73.5 |
| No stress    |               |      | $M_c$         | 66.0 |
| Under stress | $M_s$         | 64.0 |               |      |

Fig. 1—Resistivity-temperature curve for single crystal Au-Cd alloy containing 47.5 atomic pct Cd.

with and without stress, is shown in Fig. 1. The stress was applied by bending the specimen (approximately  $\frac{1}{8}$  in. sq in cross-section) 0.1 in. (maximum displacement measured at the middle of the specimen) over a span of about 1.5 in. The temperature of beginning of transformation, according to Fig. 1 with and without stress, is summarized in Table I.

The change in electrical resistivity of the Au-Cd single crystal (containing 49.0 atomic pct Cd) on repeated cooling and reheating through the transformation temperature range is shown in Fig. 2. Figs. 1 and 2 were both obtained under conditions of multiple interface transformation.

The electrical resistivity of the 47.5 pct Cd alloy decreases on transformation to the orthorhombic phase while the electrical resistivity of the 49.0 pct Cd alloy increases on transformation to the tetragonal phase.

**Stress-Strain Curves:** A typical load-deformation curve in the bending test of a specimen transformed (multiple interface) from a single crystal of Au-Cd alloy containing 47.5 atomic pct Cd is shown in Fig. 3. The load was applied at the middle of the specimen about  $\frac{1}{8}$  in. sq in cross-section over a span of about 1 in. The load in pounds was plotted against maximum deflection in inches in Fig. 3. The load  $P$ , maximum deflection  $Y$ , modulus of elasticity  $E$ , moment of inertia  $I$ , and the length of specimen between the two supports  $l$ , are related by the following equation:

$$Y = \frac{-Pl^3}{48EI} \quad [1]$$

The effective modulus of elasticity  $E$  of the  $\beta'$  specimen at different stages of bending was calculated according to eq 1 from the respective  $\Delta P/\Delta Y$  values evaluated from the slopes of the small hysteresis loops (see Fig. 3). The calculated  $E$  values are summarized in Table II.

**Motion Pictures of Interfaces:** Motion picture studies of the appearance and motion of interfaces between the  $\beta_1$  and  $\beta'$  phases during transformation were made. These studies included specimens in which the transformation was of the single-interface as well as the multiple-interface kind.

In the case of multiple-interface transformation, plates of the orthorhombic phase appear abruptly during cooling through the transformation range, as is shown in Fig. 4. The rate of formation of these plates is shown here in a succession of four frames from the movie film. The black line extending from

Fig. 2—Resistivity-temperature curve for single crystal Au-Cd alloy containing 49.0 atomic pct Cd.

Fig. 3—Load-deflection curve of  $\beta'$  Au-Cd alloy containing 47.5 atomic pct Cd.

the center of the field vertically upward to the periphery is a reference line not belonging to the specimen. No plate extends across the reference line in Fig. 4a. The next frame (Fig. 4b) shows the formation of one plate. The third frame (Fig. 4c) shows the formation of a second plate. In later frames, shown in Fig. 5, these plates grow in thickness and other plates appear which are not parallel to those shown in Fig. 4, until the specimen is apparently completely transformed.

The substantially different state of affairs with the carefully annealed crystal is illustrated in Fig. 6, in which is shown a plane interface between the two phases in a partly transformed crystal. This interface extends completely out to the free surfaces of the specimen. In this case the interface geometry undergoes no obvious change as the transformation proceeds. Correspondingly, the amount of transformed material increases fairly smoothly with time as the specimen temperature is changed. Even in this case, however, there are perceptible irregularities in the interface motion, which are more pronounced for the transformation on heating than on cooling. This homogeneous transformation by slow

movement of an interface between the two phases is not to be confused with isothermal transformation. The interface moves under the condition that the temperature of the specimen is continuously changing. Preliminary measurements show that the rate of movement of the interface is almost directly proportional to the rate of change of temperature of the specimen. Another phenomenon observed in the case of single-interface transformation is stabilization. When, for instance, the temperature of the specimen is arrested on heating, the interface movement stops and no further transformation occurs until the specimen is heated to a slightly higher temperature than the temperature of arrest.

### Discussion

*Mechanism of  $\beta_1$ - $\beta'$  Transformation:* The atomic movements and crystallographic mechanism in-

involved in the  $\beta_1$ - $\beta'$  transformation of the Au-Cd alloy containing 47.5 atomic pct Cd will be separately discussed in another paper.<sup>12</sup> The crystallographic mechanism was experimentally evaluated as a simple homogeneous shear  $(\bar{3}31)_{\beta_1} [323]_{\beta_1}$  of about  $3^\circ$  plus a possible homogeneous contraction of about 0.015  $kX$  units along the  $b$ -axis of the orthorhombic cell. This crystallographic mechanism yields almost exact agreement between the calculated and experimentally measured values of the cell dimensions of the orthorhombic phase.

*Nucleation:* The effect of stress on the temperature of beginning of transformation illustrated in Fig. 1 shows that nucleation in this diffusionless transformation is strongly influenced by the state of stress present in the specimen. Although the effect of stress on transformation has been discussed

by several investigators, such as Scheil<sup>7</sup> and McReynolds,<sup>8</sup> the data shown in Fig. 1 are the only available data demonstrating the effect of stress during a whole hysteresis cycle.

According to Fig. 1 the effect of the stress distribution on the transformation on heating is somewhat different from its effect on the transformation on cooling. In the first case transformation starts at a lower temperature but goes to completion at a higher temperature than in the stress-free case. On cooling, however, the transformation starts at a higher temperature but goes to completion at approximately the same temperature as it does for the same specimen not under stress. This difference between the effects of stress on the  $\beta_1 \rightarrow \beta'$  and the  $\beta' \rightarrow \beta_1$  transformations can be understood if one considers that a shear stress cannot oppose the transformation from cubic to orthorhombic, but can oppose the reverse transformation. Corresponding to any particular plane and direction of transformation shear, it is possible for the cubic to orthorhombic transformation to occur on the same plane but in the reverse direction. Thus if an applied shear stress opposes transformation in one of these directions, it must aid transformation in the other.

Because of the lower symmetry of the orthorhombic phase, transformation to the cubic phase by simply reversing the direction of shear on a particular plane cannot occur. Now since the specimen on which the data of Fig. 1 were obtained had originally been transformed to the orthorhombic phase by the multiple interface mechanism with no applied stress, the variously oriented regions of orthorhombic phase included some so oriented that the applied stress aided the reverse transformation. These regions accounted for the beginning of transformation at a lower temperature than that observed when no stress is applied to the specimen. Conversely, regions of the orthorhombic phase so oriented that the applied stress opposed the transformation shear transformed at a higher temperature than when no stress is applied. This discussion is, of course, based on the premise that the original cubic single crystal is produced by the orthorhombic to cubic transformation, as has always been observed in this investigation.

On the basis of the above discussion it might be expected that loading the specimen in bending would raise not only the temperature at which the transformation starts on cooling but also the temperature at which it goes to completion. On the other hand, near the neutral axis the stress is low, and correspondingly the material located here will transform at essentially the same temperature as when no stress is applied.

This interpretation of the effect of stress on the transformation characteristics is supported by the observation that was made that a straight rod of the cubic phase acquired a permanent set if it was cooled through the transformation under stress. This permanent set disappeared and the specimen again became straight when reheated to the cubic phase, even when the specimen was still stressed in bending.

Perhaps the most important evidence that this diffusionless transformation is nucleated by residual stresses, or certain types of imperfections, lies in the fact that a specimen which transforms with many interfaces may be made to transform with a single interface (i.e., the formation of an interface at one end of the specimen and movement of this interface

toward the other end of the specimen until complete transformation) by long annealing. Second, a specimen which transforms with a single interface may lose this characteristic by improper handling, only to be brought back again by annealing. These phenomena cannot be readily interpreted by the thermodynamic theory of embryo nucleation recently advanced by Fisher, Hollomon, and Turnbull.<sup>13</sup> It appears rather that the nucleation of the low-temperature phase on cooling is primarily dependent on the existence of imperfections in the specimen which perhaps had their origin in growth from the melt or in previous plastic deformation.

*Transformation with a Single Interface:* The transformation of a well-annealed single crystal of the 47.5 atomic pct Cd alloy by the motion of a single interface from one end of the specimen to the other represents a diffusionless phase change with the simplest possible geometry. The volume of stable phase grows at the expense of the unstable phase by the displacement of a single plane interface of unchanging area. One of the aspects of this transformation which must be accounted for is the fact that it does not proceed isothermally, and, in fact, if a partly transformed specimen is held at constant temperature the interface becomes stabilized against further displacement.

It appears that some relaxation process occurs at or near the interface which lowers the interfacial energy and thus the free energy of the sample. Before this relaxation occurs the free energy of the specimen at constant temperature is a straight-line function of the amount transformed and hence of the position of the interface. After relaxation the graph of free energy as a function of interface position possesses a relative minimum at the actual position of the interface.

This behavior might be likened to the rolling of a steel ball down an inclined plane which is coated with a soft material into which the ball sinks. The ball becomes stuck unless it is rolling rapidly. In the transformation experiments discussed in this paper, however, a rapid motion of the interface is precluded by the latent heat of the phase change. Since the transformation is observed at a temperature only about  $10^\circ$  from the thermodynamic equilibrium temperature at which the bulk free energies are equal, rapid and hence adiabatic transformation is not possible. An upper limit to the rate of transformation is set by the rate at which the latent heat is conducted away. No direct evidence as to the nature of this relaxation process at the interface has yet been obtained.

*Imperfections Caused by  $\beta_1$ - $\beta'$  Transformation:* A typical back-reflection Laue photogram of a  $\beta'$  specimen transformed by the motion of a single interface from a single crystal of  $\beta_1$  is shown in Fig. 7. The spots seem to be sharp and the Laue zones are rather well defined.

In the case of complex transformation with many interfaces, however, the formation of differently oriented regions (see Fig. 5) will give rise to misfits at places where these regions meet. The strain due to these misfits or imperfections presumably causes the phase to follow the opposite path on its reverse transformation to the  $\beta_1$  phase, as is experimentally observed.

The generation of imperfection in the low-temperature phase by diffusionless transformation is reflected in the electrical resistivity data shown in

Fig. 7—Back-reflection Laue photograph of  $\beta'$  crystal transformed with a single interface from a single crystal of  $\beta_1$ . X-ray beam almost parallel to  $[111]$  direction of  $\beta'$ .

Fig. 2 for the Au-Cd alloy containing 49.0 atomic pct Cd: the electrical resistivity of the tetragonal low-temperature phase at a given temperature increases successively after each transformation cycle while the temperature of the reverse transformation to  $\beta_1$  phase decreases successively after each transformation cycle. Both the electrical resistivity of the high-temperature  $\beta_1$  phase (at a given temperature) and the temperature of transformation into tetragonal phase, however, remain unchanged by cyclic cooling and reheating. The electrical resistivity of the tetragonal phase after transformation decreases slowly with time (finally reaching a stabilized value), meanwhile the temperature of reverse transformation to the  $\beta_1$  phase increases, indicating that the imperfections generated in the tetragonal phase become less effective in nucleating the reverse transformation. A similar phenomenon was also observed in the Au-Cd alloy containing 47.5 atomic pct Cd.

The rubberlike properties of the  $\beta'$  orthorhombic phase may be seen from the stress-strain curve shown in Fig. 3. First, it has an extraordinarily low effective modulus of elasticity, about  $1 \times 10^6$  psi; and, second, the effective elastic modulus increases slowly with increasing stress. The most probable explanation of this rubberlike behavior of the orthorhombic phase when it consists of variously oriented regions, all transformed from one cubic single crystal, appears to be that it represents displacement of the interfaces between the differently oriented regions. This displacement is in such a direction that favorably oriented regions increase in size at the expense of less favorably oriented ones. In this connection, "less favorably oriented" means so oriented that the applied shearing stress tends to shear the region back toward the high-temperature cubic structure. When observed under the microscope during bending, changes in surface contour are seen that can be interpreted as interface displacements of this kind.

When the stress applied to the specimen is released, the boundaries between the variously oriented

regions return to their original positions and the specimen regains its original shape.

The origin of the force which makes the interfaces return to their original positions probably is related to a relaxation process which occurs at or near the interfaces between the differently oriented regions. This relaxation process may be essentially the same as that discussed above with reference to the motion of the single interface between the two phases. Additional evidence for this relaxation process is furnished by the observation that immediately after a specimen has been transformed to the orthorhombic phase it is not rubberlike, but is very soft and takes a permanent set. Apparently the boundaries between the differently oriented regions stay in their new positions after the release of the applied stress if they are moved before the relaxation occurs. This permanent set is recoverable, however, for it disappears as the specimen is transformed back to the cubic phase.

The rubberlike behavior was not found in the low-temperature tetragonal phase of the Au-Cd alloy containing 49.0 atomic pct Cd. Apparently this behavior is characteristic of the orthorhombic  $\beta'$  phase.

### Summary and Conclusions

The mechanism of diffusionless transformation in Au-Cd single crystals containing about 50 atomic pct Cd was investigated by means of X-ray analysis of the orientation relationships, electrical resistivity measurements, and motion picture studies of the movement of boundaries between the new and old phases during transformation. The mechanism of diffusionless transformation and the generation of imperfections by diffusionless transformation were discussed. The results of this study also suggest the need of further investigation of the nature of imperfections present in the parent alloy and the type of imperfections generated in the product by diffusionless transformation.

# Atomic Relationships in the Cubic Twinned State

by W. C. Ellis and R. G. Treuting

The twinned state is characterized by a lattice of coincidence sites. Imperfections are required at stable lateral twin interfaces. Twinned regions can occur with relative ease in the diamond cubic structure.

IN recent contributions<sup>1, 2</sup> on the origin and growth of cubic annealing twins, attention has been directed to the orientation relations between such twinned components and their parent matrix. There are some aspects of twinning which may be illuminated by a more detailed consideration of the twinned state<sup>3</sup> alone. As an extreme example, the dense twinning in cast ingots of germanium,<sup>4</sup> as contrasted with the rarity of twins in cast face-centered cubic metals, is yet to be accounted for. It has been this that has led us to the present work, which, it will be noted, uses methods and constructions in many respects similar to those of Kronberg and Wilson.<sup>1</sup>

In the cubic systems, a  $70^\circ 32'$  rotation about a  $\langle 110 \rangle$  axis is angularly equivalent, as to twinning, to the more usually considered  $180^\circ$  rotation about a  $\langle 111 \rangle$  axis. Figs. 1 and 2 show a  $(110)$  projection of a twinned face-centered cubic lattice and a twinned diamond cubic lattice. In both figures, the two adjacent planes *A* and *B*, shown by the larger and smaller circles, are sufficient to represent the entire array. In each case a section of lattice, the original atom sites of which are shown by open circles, has been rotated as indicated through  $70^\circ 32'$  to bring an original  $[\bar{1}12]$  direction into coincidence with the  $[1\bar{1}2]$  direction. The latter is the intercept on the  $(110)$  projection of the  $(\bar{1}11)$  plane normal thereto, the twinning plane. In the face-centered cubic case the rotation can be performed about an axis passing through an atom-site; the mirror plane then is also a composition plane containing atoms common to both twinned and untwinned lattices.

The diamond cubic lattice may be construed as two interpenetrated face-centered lattices. Its  $\{111\}$  planes recur in a sequence of alternately short and long interspacings. Consequently a mirror plane for twinning cannot be a composition plane, but must be the bisector of one of the spacings. When the longer spacing is selected, the closest distance of approach across the mirror plane in the  $[\bar{1}11]$  direc-

tion is identical with that in the untwinned structure.

In each case periodically recurring  $(\bar{1}11)$  planes (parallel with the twinning plane) are found, on which there is coincidence of atom sites of the pretwinned and twinned orientations; these are indicated by the cross-hatched circles. In the face-centered lattice there is such coincidence every third  $(\bar{1}11)$  plane; in the diamond cubic lattice, on two adjacent planes in every six. At the twinning interface in the latter, there is on each side of the mirror plane a  $(\bar{1}11)$  plane of atoms common to both twin components. Conceivably, there is little influence on a plane of atoms about to be adhered to such a pair of coincidence planes, whether it be laid down in a normal or in a twinned position with respect to the previously formed structure. Slawson<sup>5</sup> has attributed the high incidence of twinning in diamond to this boundary state.

Further examination shows that the motion of intermediate planes can consist of various pairs of equal and opposite translations, for example of  $(\bar{1}11)$  planes in the  $[1\bar{1}2]$  direction, the familiar twinning shear, indicated in the small schematics in the figures. Since the translations form a system of shears of alternating sign between coincidence planes, twinning could take place by such a mechanism over an extended region without extensive shear; in fact, in this case any atom moves but the distance  $a_0/\sqrt{6}$  in the  $[1\bar{1}2]$  direction. One alternative construction for the face-centered cubic lattice leading to the same end result is illustrated in Fig. 3. The plane  $(\bar{1}11)$  with respect to the pretwinned orientation (the twinning plane of Fig. 1) is given, the twinned region arbitrarily bounded by  $\langle 110 \rangle$  and  $\langle 112 \rangle$  directions. The coupled shear is identical to that of Fig. 1. The "rotational" movement about coincidence sites generating the same twinned position could consist as shown of the translation  $a_0/\sqrt{6}$  for each atom of a group of three in the *B* layer in a different one of the three  $\langle 112 \rangle$  directions, and a similar translation of the underlying three atoms in the *C* layer in either the same or the opposite sense. This is not dissimilar to Kronberg and Wilson's construction for their  $22^\circ$  rotation of three adjacent  $\{111\}$  planes.

Discussion of this paper, TP 2970E, may be sent (2 copies) to AIME before April 1, 1951. Manuscript, Aug. 17, 1950; revision Nov. 21, 1950; St. Louis Meeting, February 1951.

Fig. 1—Face-centered cubic twinning, (110) projection.

On examining the body-centered cubic case, we find an analogous situation: The projection on the (110) plane is given in Fig. 4. The  $(\bar{1}12)$  twinning plane shows coincidence of sites every third layer, with a system of translations which can be coupled in one manner or another to balance within a six-layer identity period. Although there is a coincidence plane every third layer from the twinning plane, these belong alternately to (110) plane sets A and B.

### The Coincidence Site Superlattice

If the projections of twinning in the three cubic systems are examined further, it is found that in each case the twinning plane and a system of others parallel thereto are not the only planes of coincidence sites. There is in each twinned region a superlattice of atom sites common to the pre- and post-twinned orientations.

In the face-centered cubic lattice, Fig. 1, the  $(\bar{1}12)$  plane perpendicular to the twinning plane and to the plane of projection has periodic recurrence of coincidence sites and the same index type in each portion of the twin. These properties are also possessed by the other two  $\{112\}$  and the three  $\{110\}$  planes perpendicular to the twinning plane. A stereographic twinning operation also shows polar coincidence between certain  $\{221\}$  planes of the pre-twinned orientation and  $\{100\}$  of the twinned, and vice-versa; and between respective  $\{511\}$  and  $\{111\}$  planes and vice versa, among others. Under the assumed atomic relationship, these planes are also periodically atomically coincident. In such cases the difference in atomic density dictates that not all the sites of one orientation can belong likewise to the other. Thus, in Fig. 1 the  $(\bar{1}11)$  plane of the twinned region coincides with the sparsely populated  $(1\bar{1}5)$  of the pretwinned orientation. Obviously, only occasional atoms of the former can occupy sites on the latter, but all such sites are so occupied.

The coincidence site superlattice is no more than

Fig. 2—Diamond cubic twinning, (110) projection.

a possible description of the twinned state in the cubic systems, the coupled shear mechanism a suggestion as to how this state may under some circumstances be attained. Since the mechanism results in a perfect twinning relationship, it would not apply in the case of nucleation from a distorted matrix.<sup>2</sup> It would be a possible mode of twin growth in the course of grain growth following recrystallization only if the twin interface migrated with increasing grain size. Recent evidence by Burke<sup>3</sup> is in opposition to a twin interface migration. Two phenomena demonstrated by Burke, however, may be rationalized by the proposed mechanism: One of these is coalescence, in effect a detwinning mechanism; and the other the rectification of stepped twin boundaries† apparent in Burke's photographs. Each of these effects could be produced by a lateral propagation of the coupled shear mechanism in a direction to minimize the twin boundary area.

### Lateral Interfaces of Twins

In each of these cases, also, the twin has other boundaries than the twinning plane or a grain boundary. Lateral, or incoherent, boundaries are in general straight and, when enough appear in one grain, show few and preferred directions. Hence, they are probably crystallographic planes forming relatively stable interfaces. An interface of this nature might be supplied by any of the planes of the coincidence site superlattice. Each of these is occupied by atoms common to the lattices of both orientations; across such there may be a more or less disperse aggregation of atomic juxtapositions requiring readjustment to satisfy nearest neighbor distance requirements.

Thus, if as in Fig. 3, a twinned region be projected on a  $\{111\}$  twinning plane and bounded from the untwinned material by planes of the  $\{110\}$  and  $\{112\}$  types (normal to and intersecting the  $(\bar{1}11)$  projection plane in  $\langle 112 \rangle$  and  $\langle 110 \rangle$  directions respec-

† Observed by Burke. We are indebted to Dr. Burke for the opportunity to read his manuscript prior to publication.

tively), then the three  $\{112\}$  planes are seen to consist completely of coincidence sites, and atoms paired across this plane lie  $a_0/\sqrt{6}$  mutually distant. The three  $\{110\}$  planes are but  $1/3$  populated by coincidence sites and the remaining atoms are at the  $a_0/\sqrt{6}$  distance from their nearest neighbors in the untwinned region. (Greninger<sup>7</sup> has reported a  $\{110\}$  lateral twin boundary in copper.)

From the atom displacement it appears that, in twinning a perfect lattice, this close juxtaposition must be realized across any lateral boundary plane in the absence of any relieving mechanism. Since the  $a_0/\sqrt{6}$  interatomic spacing corresponds to a compressive strain of 0.423 from the normal distance of closest approach, it is plausible to consider that this circumstance does not in fact occur. Accepting this as an hypothesis, we are led to the conclusions:

Crystallographic lateral twin boundaries are sites of lattice imperfections to relieve the violation of nearest neighbor requirements otherwise occurring there. Lateral twin growth will tend to proceed until an advancing boundary generates or encounters a sufficient concentration of lattice imperfections to permit a relatively stable interface. The most probable lateral twin boundary is that requiring a minimum number of lattice imperfections to render it relatively stable. This condition is approached by a crystallographic interface having a maximum frequency of coincidence sites and a minimum frequency of nearest neighbor distance violations, but planes meeting the one criterion do not in general tend to satisfy the other.

Remarkably, this close atomic juxtaposition across potential lateral twin boundaries seems to be avoided in the diamond cubic lattice. If now in Fig. 2 we consider the twinned region to be further bounded by a  $(\bar{1}\bar{1}2)$  plane passing through coincidence sites, the closest approach of atoms in the twinned and untwinned material across this boundary is again

Fig. 3—Face-centered cubic twinning,  $(\bar{1}\bar{1}1)$  projection.

Fig. 4—Body-centered cubic twinning,  $(110)$  projection.

$\frac{a_0}{\sqrt{6}}$ . The normal closest approach in this structure is  $\frac{a_0\sqrt{3}}{4} = 0.433 a_0$ ; the strain between atoms across such a lateral twin boundary is but  $-0.058$ . However, under this construction atoms on the coincidence plane have alternately three and five nearest neighbors, a circumstance that presumably requires some adjustment and consequent strain along such a boundary. Yet the favorable trans-boundary spacing, together with the double layer of coincidence sites at the twin plane in the diamond lattice, one is inclined to associate with the multitudinous twins found in cast silicon and germanium.<sup>4</sup>

## Summary

Twinning in cubic metals can be the result of small atom displacements of a fraction of an interatomic distance on planes lying within a coincidence site superlattice. No extensive shear is required.

Imperfections are required in a stable lateral twin boundary in order to satisfy nearest neighbor distance requirements across such boundaries.

A double layer of coincidence sites along twin planes and a favorable lateral (or incoherent) trans-boundary spacing in the diamond cubic lattice pre-disposes materials having this structure to twinning.

# Transitions in Chromium

by M. E. Fine, E. S. Greiner, and W. C. Ellis

Discontinuous changes of Young's modulus, internal friction, coefficient of expansion, electrical resistivity, and thermoelectric power are evidence for a transition in chromium near 37°C. Although the X-ray diffraction pattern gives no clue, a difference between the thermal expansivity and the temperature dependence of the lattice parameter suggests a crystallographic change. Young's modulus data disclosed another transition near -152°C.

THE thermal dependence of a number of properties of chromium indicates a transition occurring over a temperature range near room temperature. Bridgman<sup>1</sup> noted this first from a minimum in the electrical resistivity near 12°C. In a sample of greater purity, Söchtig<sup>2</sup> observed the minimum at 41°C. Erfling<sup>3</sup> reported an inflection in the thermal expansivity curve at 36°C. These temperature-dependence curves are reversible with no hysteresis being detected. No discontinuity or inflection has been observed in the heat capacity<sup>2</sup> or the paramagnetic susceptibility.<sup>2</sup> Likewise, no one has noted a change in crystal symmetry.

In the present investigation Young's modulus, internal friction, coefficient of expansion, electrical resistivity, illustrated in Fig. 1, lattice constant, Fig. 2, thermal electromotive force, Fig. 3, and paramagnetic susceptibility, Fig. 4, were measured over an extended temperature range.

The samples were prepared in two ways: (1) By cold pressing a sintered electrolytic powder compact,<sup>4</sup> and (2) by electroforming from an aqueous solution. The electroformed samples were prepared by R. A. Ehrhardt and G. Bittrich by plating on copper or nickel tubes from an aqueous solution according to the method of Brenner, Burkhead, and Jennings.<sup>5</sup> The pressed powder samples (method 1) were finally annealed at 1400°C in purified helium; the electroformed samples, packed in powdered chromium, were vacuum-annealed at 1000°C.

From the composition of the original powder<sup>4</sup> the purity of the pressed powder samples is estimated to be 99.8 pct Cr. Spectrochemical analysis furnished by E. K. Jaycox, revealed only slight traces of impurities in the electroformed sample (less than 0.001 pct), neither iron nor nickel being detected. Chromium deposited by this method is reported to contain approximately 0.05 pct O.<sup>6</sup>

## Methods and Data

**Young's Modulus:** For measurement of Young's modulus, an annealed, pressed powder sample, 0.114 x 0.237 x 1.845 in., and an electroformed sample, 0.10 in. od, 0.01 in. id, and 1.86 in. long, were prepared. The resonant frequencies of the rod samples in forced longitudinal vibration were measured at a series of temperatures from -192° to 200°C by a method previously described.<sup>6, 7</sup>

Because the samples were nonferromagnetic, iron-

silicon or molybdenum permalloy tips (0.013 in. thick) were soldered to the ends. The softening temperature of the solder limited the temperature of measurement. Young's modulus,  $E_T$ , of chromium at temperature,  $T$ , may be calculated from the resonant frequency of the composite rod,  $f_T$ ; the thickness of the tips,  $t$ ; the length of the chromium sample at 25°C,  $l_c$ ; the density of chromium at 25°C,  $\rho_c$  (7.20 g per cc);<sup>8</sup> and the thermal expansivity,  $\Delta l/l_{25}$ . Modulus differences for two temperatures,  $E_T$  and  $E$ , are accurate to  $\pm 0.002 \times 10^{11}$  dynes per cm<sup>2</sup>.

$$E_T = 4\rho_c(l_c + 2t)^2 f_T^2 \left(1 - \frac{\Delta l}{l_{25}}\right)$$

Young's modulus at 25°C, Fig. 1a, is  $28.2 \times 10^{11}$  dynes per cm<sup>2</sup> ( $40.8 \times 10^6$  psi) in wrought chromium (upper curve). The modulus of the electroformed sample is apparently lower due to cracks. From the modulus measurements two transitions were observed: one with a critical temperature at 37°C, the other at -152°C.

**Internal Friction:** The internal friction,  $1/Q$ , was determined from the width,  $\Delta f$ , of the strain amplitude-frequency curve at 0.707 times the strain amplitude at resonance;<sup>7</sup> the internal friction,  $1/Q$ , then equals  $\Delta f/f$ . Fig. 1b shows a sharp peak in internal friction at 38°C. The internal friction of the electroformed sample had a similar maximum.

**Thermal Expansion:** The expansivity measurements, shown in Fig. 2, covering the temperature range -195° to +400°C were made by D. MacNair in an interferometric dilatometer<sup>8</sup> using a sample consisting of three pyramids 0.25 in. high prepared from wrought electrolytic chromium. Below -120°C the experimental points deviated up to  $\pm 2 \times 10^{-5}$  from the drawn expansivity curve in Fig. 2 because of decreased precision of the quartz wedge thermometer at low temperatures. Near 38°C the thermal expansivity curve, Fig. 2, goes through an inflection corresponding to a minimum in the coefficient of expansion, Fig. 1d, and a relative volume decrease on heating.

**Electrical Resistivity:** The variation of electrical resistivity with temperature measured by the potentiometric method is also shown in Fig. 1. The resistivity of the wrought chromium (upper curve) at 20°C is 13.6 microhm-cm; of electroformed chromium (lower curve) 12.8 microhm-cm. The lower value reflects higher purity and agrees closely with a published value.<sup>5</sup> A minimum at 40°C occurs in the resistivity curves of both samples. No conclusive evidence for a transition near -150°C was observed, but the points, Fig. 1, appear to deviate from a smooth curve between -120° and -160°C.

**Crystal Structure:** The structure of wrought chromium was investigated by the powder method in a Debye-type camera. The specimen consisted of powder filings cleaned magnetically and annealed 2 hr at 800°C in vacuum. At -190°C, chromium was found to have the same structure as at room temperature, body-centered cubic.

The lattice constants of the powder specimen were measured between -2° and 58°C in a back-reflection focusing camera.<sup>9</sup> A current of either cooled or warmed helium controlled sample temperature. Chromium  $K\alpha_1$ ,  $\alpha_2$ , and  $\beta$  (211) reflections (Siegbahn 1931) corrected for refraction<sup>9</sup> and systematic errors<sup>10</sup> were used. The precision of individual determinations is 0.003 pct. The lattice constants in Angström units<sup>11</sup> ( $10^{-8}$  cm) are plotted in Fig. 2 (inset).

The lattice constants calculated from 0°C using the thermal expansivity are shown by the dashed curve Fig. 2 (inset). The differences between the observed and calculated values, although small, appear significant and will be discussed.

**Thermal Emf and Thermoelectric Power:** The thermal emf of the chromium (electroformed)-platinum couple was measured between -200° and 103°C with the reference junction at 0°C. In the results, Fig. 3, a positive emf signifies positive current is passing from platinum to chromium at their variable-temperature junction. The slope of the thermal emf curve (thermoelectric power) shows an abrupt change at 40°C, Fig. 3.

**Paramagnetic Susceptibility:** The paramagnetic susceptibilities of an electroformed chromium tube and unannealed electrolytic chromium powder were measured at a series of temperatures, Fig. 4, by F. J. Morin. In the method, the pull of an electromagnet of known field gradient on the sample was measured with an analytical balance. The maximum flux density in the field was 5000 gauss. Spectrochemical analyses of the samples gave no trace of ferromagnetic impurities. The powder sample, however, was visibly oxidized.

The results for the two samples, shown in Fig. 4, disclose no evidence for transitions near either -152° or +37°C. (The spread among the points can be reasonably ascribed to experimental error.) The different slopes appear to be connected with the sample purity—the higher purity material has the larger positive susceptibility coefficient. Söchtig's values for electrolytic chromium powder of unstated purity agree closely with those obtained in this investigation for similar powder.

### Nature of the Transitions

From the four curves of Fig. 1, a good deal can be concluded about the transition near room temperature. It takes place over a large temperature range, progresses only as temperature is changing, within the experiment is independent of the rate of heating and cooling, and is reversible with no hysteresis being detected. (After heating the electroformed sample to 207°C, a stable modulus-temperature curve was obtained, Fig. 1.) On heating, the transition (Fig. 1) begins at approximately -20°C, increases in intensity to a critical value near 37°C, but is not complete until approximately 140°C.

Evidence for the transition near -150°C has been observed only in Young's modulus, Fig. 1. The modulus effect, taking place between -160° and -120°C with a critical temperature at -152°C, is

Fig. 1—Thermal dependence of some properties of chromium.

similar to the one near room temperature but is of much smaller magnitude.

These transitions in chromium occurring over a temperature range and without hysteresis are akin in pure metals to loss of ferromagnetism. Chromium, however, is not ferromagnetic. The small, almost constant paramagnetic susceptibility (Fig. 4) means that probably neither of the transitions are loss of antiferromagnetism.<sup>12</sup> The overlapping 4s and 3d bands in chromium suggests the transitions involve the ratio of 4s to 3d electrons. From the relative decrease in electrical resistance on heating through the transition near room temperature, Söchtig<sup>2</sup> postulated that the proportion of 4s to 3d

Fig. 2—Thermal expansivity and thermal dependence of lattice constant in wrought electrolytic chromium.

electrons, that is, the relative number of carriers, is increasing. The lack of hysteresis seems to require an electronic change of this kind. The temperature course of the transition would depend upon the electronic energy considerations determining the ratio of 3d to 4s electrons.

Referring to the transition near room temperature, the inflection in the expansivity curve, Fig. 2, is equivalent, on heating, to a decrease in sample length of approximately  $2 \times 10^{-4}$  in. per in. or, assuming isotropic expansion characteristics, a decrease in volume of  $6 \times 10^{-4}$  per in.<sup>3</sup> Because of this volume effect, increasing the pressure would be expected to lower the transition temperature. This has been observed, for Bridgman<sup>1</sup> found that increasing the pressure from 0 to 4000 kg per cm<sup>2</sup> decreased the temperature of minimum resistivity from 12° to -20°C. The transition is also influenced by sample purity. In a number of impure samples Hidnert<sup>13</sup> observed a lower temperature range and a larger volume effect.

On heating through the transition, Young's modulus is larger than the value obtained by extrapolating from below the transition, Fig. 1a. The increase in modulus may be regarded as arising from a difference between the  $U(r)$  relations at high and low temperatures (the modulus is proportional to  $\partial^2 U / \partial r^2$ ). With increasing temperature the  $U(r)$  relation (as in loss of ferromagnetism<sup>14</sup>) gradually changes from that of the low-temperature "modification" to that of the high-temperature "modification." From this consideration alone the modulus is expected to increase gradually through the transition. The observed initial negative deviation of

Fig. 3—Thermal emf and thermoelectric power of electroformed chromium (Cr-Pt couple).

Young's modulus from a usual temperature dependence, Fig. 1, implies an additional contribution to the strain. The additional strain may arise as follows: On heating through the transition there is a negative volume effect with the largest change in coefficient near the temperature of minimum modulus (37°C). The additional strain like this volume effect (compare Figs. 1a and d) increases with temperature to 37°C then abruptly decreases. In this temperature region the ratio of the two "modifications" or the completeness of the transition may well be stress-dependent. A tensile stress will then cause the transition to progress in that direction which increases the volume (toward the low-temperature "modification") and the opposite will hold for a compressive stress. The resulting volume changes give larger tensile and compressive strains. The increased internal friction at 37°C, Fig. 1b, is further evidence for a mechanism of this sort.

The difference between the observed lattice constants and those calculated from the expansion data (Fig. 2) suggests the transition involves a departure from the ideal body-centered cubic arrangement. Direct evidence of this departure has not been observed. The difference corresponds to 0.04 pct more atoms (on the average) associated with a unit cell

Fig. 4—Paramagnetic susceptibility of electrolytic chromium.

above the transition than below and an equal decrease in the proportion of unit cells. The denser packing is consistent with the observed overall increase in Young's modulus on heating through the transition. The extra atoms by short range movements perhaps assume interstitial (face-centered) positions giving the denser packing. Alternatively, denser packing could arise from disappearance of vacant lattice sites on heating.

# Effect of Heat Treatment on the Electrical Properties of Germanium

by H. C. Theuerer and J. H. Scaff

Germanium may be reversibly converted from *n* to *p* type by heat treatment. Data for the conversion and the associated changes in resistivity are given and the results are interpreted in terms of changes in the donor-acceptor balance.

**M**EANS for controlling the electrical properties of germanium in a predictable manner are of interest because of the increasing utilization of this element as the semiconducting material in electrical devices. Since both the mechanism and the magnitude of the electrical conductivity depend upon the kind and quantity of impurities present, the conductivity usually is adjusted by first carefully purifying the germanium, and then, by standard alloying procedures, adding the elements desired. The elements usually added are from the third or fifth periodic groups depending upon whether *p*- or *n*-type germanium is desired. However, in the development of germanium rectifiers during the war, it was found that it was possible also to modify reversibly the conductivity of germanium and even to produce conversion from *n* to *p* type by heat treatment.<sup>1,5</sup> Since then a detailed study of this effect has been made. The data are presented in this paper and an explanation is offered for the effects observed.

## Preparation and Experimental Procedure

The method used in preparing the germanium ingots for this investigation has been previously described.<sup>1</sup> The method consists essentially of (1) reduction of  $\text{GeO}_2^*$  and (2) preparation of a 50-g

ingot from the reduced material. Graphite containers are used in both steps. In the first step the  $\text{GeO}_2$  is reduced in hydrogen at  $650^\circ\text{C}$  to form a sponge germanium which, to assure complete reduction and to obtain massive materials, is fused subsequently in the reduction furnace by gradually raising the temperature to  $1000^\circ\text{C}$ . The button of germanium thus obtained corresponds to a yield of 99.8 pct. The final ingot is prepared by fusion of the germanium button in a helium atmosphere. A cylindrical crucible in a vertical silica tube furnace is employed and the crucible is heated by an external induction coil. The ingot is solidified from the bottom upward by raising the induction coil at a constant rate with power to the coil kept at a fixed value.

In such ingots, segregation is normal and most of the impurities are concentrated in the last region of the ingot to freeze. It follows then that the major portion of the ingot is purer than it would have been if freezing had occurred in a random fashion. Moreover the orderly advance of the freezing surface during solidification establishes in the ingot a succession of surfaces of constant composition, if it is assumed that the liquid is homogeneous and that diffusion in the solid is negligible. Therefore, some information on the distribution of impurities in the ingot may be acquired by determining the shape of the solid-liquid interface at different stages of solidification. This is of importance because the concentration of impurities will be seen to affect the response of germanium to heat treatment. Such information is difficult to acquire by direct means, for the impurities responsible for the electrical properties of germanium prepared in this way are present

\* Rectifier grade, prepared by hydrolysis of redistilled  $\text{GeCl}_4$ . Obtained from the Eagle Picher Co.

H. C. THEUERER and J. H. SCAFF, Member AIME, are Metallurgists, Bell Telephone Laboratories, Inc., Murray Hill, N. J.

Discussion on this paper, TP 2996E, may be sent (2 copies) to AIME by April 1, 1951. Manuscript, Oct. 16, 1950; St. Louis Meeting, February 1951.

Fig. 1—Shape of solid-liquid interface during the solidification of a germanium ingot.

a (above)—Initial stage.  
b (right)—After ingot is half solidified.

to the extent of only a few parts in ten million and are thus beyond the range of the usual methods of analysis.

The shape of the solid-liquid interface may be determined by preparing ingots in the standard way except that after allowing solidification to proceed for the desired time the crucible is upset to allow the remaining liquid to flow out quickly. Sections of such ingots, etched to reveal the grain structure, are shown in Fig. 1. It will be noted from these that the freezing surfaces are quite smooth and regular and that there is no sign of dendrite growth. Also it may be seen that, while solidification occurs predominately from the bottom of the crucible upwards, there is sufficient heat loss from the sides of the crucible that solidification occurs to some extent from the sides of the crucible inward. This accounts for the curvature in the solid-liquid interface.

For the heat-treating studies the 50-g ingots were cut in half through the vertical axis and from the central portion of one half of the ingot a rectangular specimen  $\frac{1}{8} \times \frac{1}{8} \times 1$  in. was cut, so that the long axis of the specimen was approximately parallel to the vertical axis of the ingot. This specimen was used for resistivity measurements by a potentiometric method. The remaining half of the ingot was used for rectification measurements. To prepare the ingot for these measurements, a large area electroplated contact was made to the rounded surface of the ingot. The cut face of the ingot was then ground flat with abrasive, etched and the surface explored with a tungsten point under a controlled load. By measuring the current through the contact when the direction and magnitude of the applied voltage was changed, it was possible to differentiate quickly between *n*- and *p*-type germanium. Typical rectification patterns obtained in these tests are shown in Fig. 2.

The rectification pattern of Fig. 2 for *n*-type germanium is typical of that of a "high back" voltage rectifier. It will be noted that in the reverse direction (Ge positive with respect to the point) little current flows even at voltages as high as 50v. With increasing applied voltage, larger currents flow and a value is finally reached where further increases in voltage result in a reduced potential drop across the rectifying junction. The peak voltage which the

junction will support is one way of characterizing the properties of germanium as will be seen in the following section.

The half section of the ingot and the companion resistivity specimen prepared as described were heated at successively higher temperatures between 500° and 900°C for periods of 24 hr in a quartz tube in which a helium atmosphere was maintained. After each treatment the specimens were rapidly cooled to room temperature by removing the quartz tube from the furnace and allowing it to cool in still air. The surfaces of the specimens then were ground and etched prior to measurement of the conductivity type and resistivity. At several of the temperatures after the initial 24-hr treatment, the specimens were reheated for an additional 48 hr and the conductivity type and resistivity were remeasured. No significant changes were observed as a result of the second treatment, indicating that a steady state is reached at these temperatures in a 24-hr period. After the samples had been treated at 900°C, they were reheated at several lower temperatures between 900° and 400°C for 24 hr each, again measuring the properties after each heat treatment.

#### Effect of Heat Treatment on Conductivity

In the as-cast state the germanium ingots are *n* type throughout with peak reverse voltages ranging between 50 and 200 v depending on position in the ingot. This is illustrated schematically for ingot sections in Fig. 3, in which the contour lines show regions in the ingot which have the peak reverse voltages listed. The similarity in shape between the contours of peak reverse voltage and the contours of the freezing surface at different stages in solidification, given in Fig. 1, is at once apparent. The peak reverse voltage is highest near the bottom of the ingot and lowest near the top of the ingot. From this it is evident that the peak reverse voltage of the germanium is systematically related to its purity.<sup>2</sup>

If the germanium ingot is heat treated at temperatures above 550°C and cooled to room temperature, in the manner previously described, part of

the ingot transforms to *p*-type germanium. Such material has a poor rectification characteristic with tungsten points, and does not support high voltages in either direction. The regions of the ingot which transform from *n* to *p* type as a result of the various heat treatments and the peak-voltage contour lines for the untransformed *n*-type regions are also given in Fig. 3. It should be recalled that, because of the solidification procedure used in preparing the ingots, the purity decreases progressively from bottom to top of the ingot. The data of Fig. 3 show that the purer material in the ingot converts to *p* type at the lowest temperature of treatment. Higher temperatures of treatment are required to convert those regions in the ingot of lower purity. The general curvature of the *n/p* boundaries after heat treatment suggests again that these are regions of equal purity formed during the freezing process. It will be noted that even at temperatures as high as 900°C, the impurity-rich top of the ingot is not converted to *p* type.

The thermal conversion of germanium from *n* to *p* type is completely reversible. Fig. 3 shows, for example, that the amount of *p* material in the ingot and the peak-voltage contours are the same after a 600°C treatment, whether or not the sample had previous high-temperature treatments. Also, although the specimen had been treated for a total of 96 hr, a final heat treatment at 500°C resulted in material having the same characteristics as that after the initial 500°C treatment. This would not be expected if a substantial diffusion of the impurities initially in the ingot had occurred during the course of the treatments.

Large changes in resistivity are also produced by the heat treatment. Resistivity data for materials from three positions in an ingot are given in Fig. 4. Several features of the curves are to be noted. The resistivity is highest for the purer material at the bottom of the ingot and lowest at the top. As the temperature of treatment increases, resistivity rises reaching a maximum at the *n/p* conversion point. For higher temperatures of treatment the resistivity falls rapidly and reaches a relatively low value after treatment at 900°C. The divergence in the three curves tends to decrease for the higher temperatures of treatment. The resistivity after treatments between 500° and 900°C is independent of previous thermal history and depends only on the final temperature of treatment and on the location of the material in the ingot. Finally the transition temperature for *n/p* conversion increases as the impurity level increases.

Other experiments had shown that the resistivity had reached a constant value after treatment at 500°C for 24 hr. For lower temperatures of treatment, the changes occur much more slowly as shown by data for treatments for various periods of time at 360° and 400°C. For both series of measurements the specimens were first heated to 900°C for 24 hr and rapidly cooled to obtain *p* germanium. They were then reheated at 360° or 400°C for different intervals of time, cooled to room temperature, and measured. These data are given in Table I and in Figs. 5 and 6.

With increasing time of treatment at 360°, a gradual increase in resistivity is observed and after 1084 hr of treatment the upper third of the specimen transformed to *n* type. At 400°C the material is converted to *n* germanium after 24 hr. At this temperature about 500 hr are required for resistivity to

Fig. 2—Typical rectification patterns for *n* and *p* germanium with tungsten point contacts.

reach a constant value. It is to be noted that the terminal values of resistivity after treatment for 1000 hr at 400° are the same as those obtained initially after treatment at 500°C for 24 hr.

### Proposed Mechanism for the Effect of Heat Treatment

It is now well established for both silicon and germanium that *p*-type or *n*-type conduction results if impurities from the third (acceptors) or fifth (donors) periodic groups respectively are present.<sup>3</sup> The conductivity at room temperature is proportional to the number of impurity atoms present. *P*-type conductivity may also result from acceptor levels introduced by lattice defects produced, for example, by physical displacement of germanium atoms from their normal lattice sites.<sup>4</sup> Moreover if donor and acceptor levels occur simultaneously, a compensating action occurs so that the mechanism and magnitude of conductivity depends upon which carrier is in excess and on its net concentration. It is apparent, therefore, that the changes in the properties of germanium on heat treatment are due to a change in the donor-acceptor balance. If we assume, for example, that the concentration of acceptors depends upon the temperature of heat treatment, then for *n*-type material, as the temperature of heat treatment is increased, the acceptor concentration rises and the net donor concentration falls so that an increase in resistivity is observed. The resistivity reaches a maximum after treatment at

Fig. 3—Effect of different heat treatments on the conductivity type of germanium.

Fig. 4—Effect of temperature of treatment on the resistivity of germanium from different positions in an ingot.

the temperature where the donors and acceptors just balance or compensate one another. For treatments above this temperature acceptors are in excess and the material is *p* type, and, since the acceptor concentration continues to increase with increasing temperature of heat treatment, the resistivity accordingly decreases. This hypothesis adequately explains the shape of the curves of Fig. 4 and the same argument may be used to explain the curves of Fig. 6. Following the argument further it would be expected that the temperature of conversion from *n* to *p* type would be lowest for material with the lowest initial concentration of donors. This is actually the case as shown by the curves of Fig. 4. This also explains the variation in resistivity with location found in ingots heat treated so that the lower part is *p* type and the upper part *n* type (e.g., the 600° treatment, Fig. 3). In this case the resistivity of the *p*-type material is low at the bottom of the ingot and increases as the

*p/n* boundary is approached. The resistivity then falls as the top of the ingot is approached. It is believed that treatment at 600°C increases the acceptor concentration uniformly in the ingot just enough to convert the bottom portion of the ingot to *p* type. In this region of the ingot the concentration of acceptors must exceed that of the donors. Since, however, the donor concentration increases with height in the ingot, the excess of acceptors over donors in the *p* region decreases with height. Hence the resistivity rises in this region as the *p/n* boundary is approached. Above the boundary, the donor concentration exceeds that of the acceptors and in this region the concentration of donors in excess of the acceptors increases progressively with height in the ingot. The resistivity accordingly decreases with height in the *n* region.

The essential feature of the above explanation is that the number of acceptor levels or "holes" depend upon heat treatment. Two mechanisms by which this could occur are known. In the one mechanism, essentially chemical in nature, heat treatment is supposed to change the effective concentration of acceptor impurities as, for example, by a change in solubility with temperature. The other mechanism

\* Material converted to *n* type.

is essentially physical in nature. It has been shown<sup>4</sup> that bombardment of germanium by nucleons converts *n* germanium to *p* type and that the converted material may be transformed to the original *n* type by heat treatment at low temperatures. The bombardment is supposed to break the valence bonds by displacement of atoms in the lattice to form defects or "holes" which compensate the existing donors and ultimately result in conversion to *p* type. Beyond the conversion point further bombardment introduces additional defects which further increase the conductivity. According to this view, heat treatment at low temperatures, of the order of 500°C, allows these defects to be "healed" with reversion to the original properties. If the defects created by heating the germanium to temperatures above 500° are retained on cooling to room temperature, then this physical mechanism would also account for the results of the present investigation. Additional experiments are required to determine which of these mechanisms is correct.

### Summary

It has been shown that germanium may be reversibly converted from *n* to *p* type with accompanying changes in resistivity by appropriate heat treatment. The results have been interpreted in terms of changes in the balance between acceptors and donors resulting from an increase in acceptor

Fig. 5—Effect of heat treatment at 400°C on the conductivity type and peak reverse voltage of thermally converted *p*-type germanium.

Fig. 6—Effect of heat treatment at 400°C on the resistivity of thermally converted *p*-type germanium from different positions in the ingot.

levels as the temperature of heat treatment is increased.

Two mechanisms for the increase in acceptor concentration have been given, one postulating a change in solubility of an acceptor impurity, the other postulating the formation of acceptor centers by thermally produced lattice defects.

### Technical Note

## Grain Boundary Effect In Surface Tension Measurement

by Harry Udin

IN 1948, the writer and his associates determined the surface tension of solid copper by balancing the force of surface tension in a very fine wire against an external load.<sup>1</sup> At that time we, in common with other early workers, assumed that grain boundary energy in a pure metal is very small in comparison to the energy of an external surface. Accordingly, we neglected the internal surface energy of the coarse-grained specimens.

Since that time, experimental evidence has accumulated showing that grain boundary energy, far from being small, is generally about one-third of the energy of an external surface.<sup>2-4</sup> This is sufficient to introduce a significant error into our determination. The differential equation governing equilibrium is:

$$w dl = \gamma ds_1 + \gamma^* ds_2 \quad [1]$$

rather than

$$w dl = \gamma ds$$

as originally written.  $w$  is the balancing force in dynes,  $l$  the length of the specimen,  $s_1$  the external and  $s_2$  the internal surface area,  $\gamma$  the copper/copper vapor surface tension, and  $\gamma^*$  the grain boundary tension.

Fortunately, we had made for another purpose a careful study of the size and shape of the grains, and found that the boundaries, with rare exceptions, traversed the specimens and were perpendicular to the wire axis. For this case, eq 1 leads to

$$w = \pi r \gamma - \left( \frac{n}{l} \right) \pi r^2 \gamma^* \quad [2]$$

where  $r$  is the wire radius and  $\left( \frac{n}{l} \right)$  is the number of grains per unit length. A count of some twenty 5-mil wires indicated that  $\frac{n}{l}$  became  $80 \pm 10$  after

a short anneal near the melting point, and remained nearly constant for as long as 96 hr at temperature.

An assumption of  $\gamma^* = 1/3\gamma$  leads to a defining equation for  $\gamma$ :

$$w = \pi r \gamma \left[ 1 - \left( \frac{n}{l} \right) \left( \frac{r}{3} \right) \right] \quad [3]$$

The term in the brackets may be considered a correction factor applied to eq 11 of ref. 1. Upon applying this factor, the surface tension of solid copper at its melting point is found to be  $1650 \pm 100$  dynes per cm, rather than 1370 as previously reported.<sup>1</sup> The new temperature coefficient is  $-0.55$  dynes per cm per °C.

Grain boundary energy is more significant than surface energy to the physical metallurgist. It is evident from eq 2 that a series of experiments with wires of different grain size can lead to an evaluation of  $\gamma^*$ . The details of such an experiment are being worked out now.

# Crystallographic Angles For Magnesium, Zinc and Cadmium

by Edward I. Salkovitz

THE determination of the orientation of metal single crystals and the studies of plastic deformation are greatly facilitated by the use of the stereographic projection. To draw a standard projection of the crystal it is necessary to have a tabulation of the angles between the various crystallographic planes of the particular crystal studied. Bozorth<sup>1</sup> has published such a table for the cubic system which can be found in many reference books; such convenient tabulation for the hexagonal metals, however, does not appear to be in the literature, although scores of workers have calculated these angles. Therefore, Table I of angles for magnesium, zinc, and cadmium has been compiled. Since the *c/a*

Fig. 1—Standard (0001) projection for zinc hexagonal *c/a*=1.856.

ratio is different for each of these metals, three separate calculations are necessary.

The angles  $\phi$  between (*HKIL*) and (*hkil*) were calculated by means of the formula:

$$\cos \phi = \frac{Hh + Kk + \frac{1}{2}(Hk + hK) + \frac{3}{4} \frac{a^2}{c^2} Ll}{[(H^2 + K^2 + HK + \frac{3}{4} \frac{a^2}{c^2} L^2)(h^2 + k^2 + hk + \frac{3}{4} \frac{a^2}{c^2} l^2)]^{1/2}}$$

The *c/a* ratios were calculated from data given in the 1948 edition of Metals Handbook. Fig. 1 is a typical (0001) standard projection of zinc. For all practical purposes, it serves for cadmium as well, as can be seen from the table. For magnesium, however, it is necessary to construct another net.

# Observations on Rimming Steel Ingots

by A. Hultgren, G. Phragmen, S. Wohlfahrt and J. E. Ostberg

Detailed study was made of a number of rimming ingots, both low and high carbon, and especially upon effects of superimposed air pressure. Requirement to suppress core bubbles is between 10 and 15 atm; at 6.5 atm freezing was in semikilled manner and at 3 atm, steel was of rising type. Probable mechanism of freezing under various conditions is discussed.

AN earlier paper<sup>1</sup> reported an investigation made by a committee for studying rimming steel ingots appointed by Jernkontorets in Stockholm. The present paper is the outcome of some further work done by the same committee.

Since the characteristics of ordinary rimming steel are connected closely with the amount of gas liberated during freezing and since this amount of gas is governed by the pressure, it was considered of interest to ascertain in what manner and to what extent definite pressures applied to the top of the liquid steel in the mold would affect the solidification process and the consequent structure of a rimming steel of ordinary composition.

The experiments were made at the Domnarfvet Steel Works. The steel was made according to normal practice in a 4-ton Rennerfelt electric furnace. Ferromanganese was added in the furnace; no aluminum was added, with one exception. Analyses of the four heats are given in Table I.

The top-poured ingots measured about 12 in. sq x 48 in. and weighed about 1300 lb. One or two ingots of each heat were allowed to solidify under pressure, using a special device for admitting compressed air to the upper closed part of the mold, as shown in Fig. 1. A heavy plate sealed with asbestos was bolted to the top of the mold. The plate had a tapered aperture for pouring. Immediately after pouring the hole was closed by a wedged plug, and compressed air was admitted through a hole in the plug. Because of some delay in applying the plug, full pressure was not reached immediately. The pressure was adjusted to the desired value as indicated by a manometer. In order that the interior of the

ingot might have the benefit of the pressure, the freezing of the top crust was delayed by a refractory lining applied to the top part of the mold, Fig. 1. Ingots were also cast from each heat without applied pressure, and with and without refractory lining at the top.

Axial sections of ingots were cut either of the whole ingot or of some part of it of special interest; sections were polished and usually etched.<sup>1</sup>

To facilitate description of structures the following terms may be used for different types of ingots solidified under gas evolution:

1. *Box-hat or boot-leg ingot*: Abundant gas evolution during casting and during rimming; no rim holes.
2. *Normal rimming ingot*: Lively gas evolution during rimming; usually rim holes in lowest part of

Fig. 1—This test mold shows the arrangement for freezing under pressure. To insure the benefit of pressure to the interior of the ingot, freezing of the top crust is delayed by a refractory lining at the top of the mold.

ingot, the volume of which roughly balances shrinkage during solidification of rim zone, with the result that the top surface retains about the same level during rimming.

3. *Rising ingot*: Moderate gas evolution during rimming period causing rim holes to form along more than half the ingot, their total volume exceeding shrinkage in this period and thus causing the top surface to rise continuously.

4. *Semikilled ingot*: Slight gas evolution; the gas evolved remains wholly or largely as blowholes, usually oblong and located in upper half of ingot, where ferrostatic pressure is low enough for gas

Table I. Composition of Test Heats

liberation; when blowhole volume balances shrinkage no pipe cavity is formed.

### Results

*Heat J 7521: Ingot 7521-5, No pressure applied, no refractory top lining, Fig. 2:* Only the top 18 in. was sectioned. Rim holes are absent, which is normal. Rim channels are present after passing into small blowholes at the inner end. There is a large cauliflower or nigger head at the top.

*Heat J 7521: Ingot 7521-3, No pressure applied, refractory top lining, Fig. 3:* The structure indicates that the mold was filled to about 4 in. beyond the beginning of the lining. During rimming the level of the steel rose about 4 in. Later, liquid metal penetrated the top crust, forming a cauliflower.

Rim holes terminate only 10 in. below the lining; their length decreasing continuously from the bottom end upward. The inner part of the rim zone bordering on the intermediate blowholes is almost solid, like the uppermost part. The rising top level and the larger total rim-hole volume are obviously connected.

The core contains many blowholes, their volume being related to the volume of liquid steel that escaped through the top crust. In the lower third of the core, the core holes form pointed V patterns, to be explained as follows: After this part had reached a late stage of solidification and had developed numerous large blowholes, solidification proceeded further toward the top under pressure, causing the still deformable bottom aggregate to give way, its blowholes being compressed.

A few large vertical blowholes are also seen along the axis in the lower part. Their volume equals the

sum of the shrinkage and the compression of the surrounding blowholes during the final freezing period. These central blowholes seem not to have been compressed, probably because the stiff metal aggregate at this late stage resists the higher pressure from above.

The gas pressure of a freezing steel is a function of the composition of the mother liquor from which gas is evolved. The cause of the vertical pressure gradient postulated probably was the fact that, through sedimentation of suspended crystals, the lower portion of the core at a given temperature during freezing contained less mother liquor than the upper portion and, in consequence, its final degree of segregation was less.

The fact that this ingot rose during rimming indicates that less gas was evolved in unit time than in ingot 7521-5 during this period, possibly because of retardation of freezing by the top lining.

*Heat J 7521: Ingot 7521-4, applied pressure, 15 atm:* Full pressure was reached 1 min-22 sec after the end of casting. Fig. 4 shows the distribution of blowholes and Fig. 5 the etched section of half the top portion, by oversight not annealed.\* A columnar structure is faintly visible in the etched surface. This is not the primary structure but the austenite structure formed during cooling. (The true primary structure of a section taken about half height is seen in

\* Usually, in order to obliterate the traces of secondary ( $\gamma$  transformation) structure, the sections were heat treated by heating to about 1000°C, water quenching, and tempering several hours at 700°C.

Fig. 7—Section of the top of Ingot 7521-2, not heat treated. Columnar secondary structure was observable in the original. Applied pressure was 10 atm.

Fig. 6; this section was heat treated.) In Fig. 5 is seen a lower set of wide rim holes beginning near the surface and ending about 1 in. beneath it.

These rim-holes had begun to form before pressure was applied and afterwards continued to grow until the total pressure reached was sufficient to suppress gas evolution. Farther upward a short set of blowholes appears beginning about 0.6 in. beneath the surface. The solid 0.6 in. surface layer is of the type common in the upper part of rimmed ingots; it indicates ample gas evolution. With the exception of the blowholes described, the ingot section is solid up to the funnel-shaped porous region at the top, Figs. 4 and 5, probably formed by the top crust, as shrinkage proceeded, being forced downward like a cork in a bottle.

The primary structure displayed in Fig. 6 enables a detailed study of the mode of freezing. The rim holes show the well-known alternate constrictions and expansions. Their inner end is flattened and terminated by a "segregation button." Each blowhole temporarily reached farther inward and, owing to the rising pressure, a portion of a partly frozen mass was pressed into it and some mother liquor was squeezed out, forming the button.

In a zone farther inward, occasional extensions of rim holes occur as well as separate rounded blowholes, without visible connection with the rim holes. The latter also are flattened at their inner ends and have a button segregate. In addition, a steeply

sloping string of segregate is often attached to such a blowhole. The latter blowholes probably formed under rising pressure in the following way: During the rimming period a great many gas bubbles detach and rise. By the resulting rapid upward movement of the liquid metal, the mother liquor at the solidification front is largely removed and mixed with the main mass of the liquid. In other words, the liquid metal into which the crystals grow is relatively little segregated. As the pressure rises, gas evolution stops, hence movement of the liquid also. During subsequent freezing in quiet liquid two simultaneous changes occur: (1) pressure rises continuously, and (2) the mother liquor at the front is rapidly enriched in alloying elements, including carbon and oxygen. Gas evolution is suppressed by 1 and promoted by 2. When the effect of 1 predominates the growth of the rim holes is stopped; their inner ends are compressed; and depressions form in the solidification front opposite the blowholes. If, however, 2 overtakes 1, owing to the slow rise of pressure, new blowholes appear, preferably in the depressions where enrichment is greater. If such blowholes are openly spaced and if they expand faster inward than the front grows, their inner ends lack support; hence they detach themselves and rise. Since, at this stage, the surrounding mass probably contains crystals, the bubble will rise slowly, displacing crystals which do not close up behind the bubble. The mother liquor in the wake of the rising bubble forms string segregate. Such steep string segregates were observed earlier in steel ingots insufficiently killed. Their absence in ordinary rimming-steel ingots is probably caused by the fact that

Fig. 8—Reverse side of section shown in Fig. 7 in the annealed condition.

rimming and movement in the liquid goes on to the stage at which the moving mass is sluggish enough to prevent the bubbles from rising.

*Heat J 7521: Ingot 7521-2, applied pressure, 10 atm: Full pressure was reached 2 min-3 sec after casting was finished.*

Fig. 7 shows the columnar secondary structure of the ingot top, not heat treated. The rim holes end 14 in. below the top insulation, consequently this ingot showed, like ingot 7521-4, greater rising tendency during rimming than ingot 7521-3, solidified without applied pressure in a mold with refractory top lining. Presumably the cap applied to the mold to some extent obstructed the reaction of the steel with the oxygen of the air, thus restricting gas evolution during rimming.

The central top area is more porous than in ingot 7521-4 (15 atm), a natural consequence of the lower applied pressure (10 atm); otherwise the interior of this ingot also is solid.

The rim holes end at a depth of about 0.6 in. beneath the ingot surface. Fig. 8 (annealed, back of section shown in Fig. 7) shows a fine dendritic primary structure extending to about 1 in. from the surface. The inner ends of the rim holes are flat or have a blunt shape. In the intermediate region farther inward are outlined extensions of the holes which have been filled and also freshly formed blowholes largely filled with a mass of coarser primary structure with continuous transition into the core structure. Up to about 3.5 in. from the surface, the core shows random dendritic patches; farther in the structure it is wholly globular. The dendritic intermediate zone indicates a scarcity of crystal nuclei in the liquid at the stage at which the rising pressure stopped gas evolution. The fact that the rim holes of this ingot are shorter than those of ingot 7521-4 is unexpected in view of the longer time for reaching full pressure.

*Heat J 7699: Ingot 7699-A, applied pressure, 6.5 atm: Full pressure was reached after 57 sec.*

Fig. 9 shows the blowhole distribution in the ingot. The external zone up to about 0.8 in., is free from blowholes but contains numerous rim channels; hence, there was more gas evolution in the early stage of freezing than in heat 7521. Inside this external zone, an intermediate zone extending to about 2 in. from the surface, shows numerous narrow blowholes, often interrupted. These were formed under rising pressure. The lower part of the core is practically solid but in the upper part are seen long narrow blowholes converging toward the center of freezing, typical of a semikilled steel ingot. In the middle portion along the axis, a set of fine cores is seen.

Freezing probably proceeded as follows: When the pressure was applied the top level sank about 8 in. The pressure was, however, insufficient for complete suppression of gas evolution. On continued freezing, therefore, the blowholes formed caused the top level to rise about 3.5 in. in 2 to 3 min. After full pressure was attained the top surface was frozen over, as judged from the thickness of the crust. At this moment the core material probably consisted of a great quantity of crystals and little mother liquor. For this reason the final stage of freezing was associated with a small amount of shrinkage and, in consequence, only small cores and few blowholes were formed. In the bottom portion, radial as well as vertical blowholes occur. The latter type of holes was seen also in ingot 7646-4 (below).

Fig. 9 (above)—Sections of Ingot 7699-A, which was solidified under pressure of 6.5 atm.

Fig. 10 (right)—Sections of Ingot 7646-4, which was solidified under a pressure of 3 to 4 atm.

*Heat J 7646: Ingot 7646-4, applied pressure varying between 3 and 4 atm: About 2 oz per ton of aluminum was added to the ladle. Full pressure was reached 50 sec after end of casting.*

Fig. 10 shows the blowhole distributions in the ingot. Freezing probably occurred as follows: Before pressure was applied, rim holes formed in the lower part of the ingot (blowhole zone I) reaching a maximum depth of 1 in. near the bottom. From the bottom toward half height the length of the rim holes gradually decreased to zero, their outer boundary moving inward and their inner boundary moving outward; the upper half of the rim zone is correspondingly nearly solid.

In the lower third of the ingot, blowhole zone I is succeeded by a solid intermediate zone about 0.4 in. thick, indicating that the sum of applied and ferrostatic pressures in this portion was sufficient for suppression of gas evolution at this degree of segregation.

Proceeding inward, the next zone is characterized by numerous long blowholes in a direction deviating somewhat in an upward direction from the perpendicular to the surface (blowhole zone II). It is assumed that, through segregation, the mother liquor has passed the composition corresponding to gas saturation at the established total pressure. These blowholes are not regarded, therefore, as rim holes. In the upper half of the ingot the solid rim zone is followed directly by blowhole zone II. This zone is followed by a solid core of about one third the ingot width. At the boundary the blowholes are often flattened or bent upwards. Along the axis and in the top part some porosity may be seen.

The great volume of the blowholes in zone II has its counterpart in a top portion formed by rising during this stage of freezing, to the extent of 6.3 in. beyond the original level before the cap stopped it. The moment of capping then corresponds to cessation of blowhole formation.

In the bottom portion, and occasionally in upper portions also, roughly vertical, long blowholes and rows of such holes are found, mostly in zone II, but a few in the core also. Probably there has been enough gas evolution for the inner ends of some of the perpendicular blowholes to detach themselves ahead of the actual freezing front and to rise slowly, their movement being retarded by the sluggish consistency of the aggregate. In other words, the perpendicular growth of a blowhole indicates that it is adequately supported by the surrounding solidified steel. The fact that the rising gas bubbles were retained as blowholes and did not move to the top is, of course, a sign of a sluggish mass. The comparative solidity of the core region also results from the small amount of mother liquor in the aggregate when rising was checked.

Reviewing the results reported above for rimming steel solidified at different pressures, it is seen that under the conditions of the experiments, an applied pressure of 15 atm was sufficient to prevent all gas liberation as bubbles in the core of the ingot, while 10 atm was not quite sufficient. Disregarding the shielding effect of the top crust in later stages of freezing, the final composition of the mother liquor in these ingots seems to correspond to an applied pressure of 10 to 15 atm. It is of course possible that some supersaturation is required before gas is liberated, in which case the equilibrium pressure was still higher. Rimming steel subjected to such pressures behaves, of course, like a killed steel during freezing. At an applied pressure of 6.5 atm, the steel froze like a semikilled steel, and at 3 atm like a rising steel.

#### Rimming Steel with High Carbon Content

Since rimming steel with about 0.40 pct C is used to some extent in Sweden, three ingots of such material were examined, two made at Degerfors and one at the Surahammar works.

*Ingots Made in Degerfors:* One top and one bottom poured ingot were available from different basic open-hearth heats; compositions are given in Table II. The compositions were similar, with the exception of phosphorus which was considerably higher in the first ingot. Casting time was about 45 sec for the

Fig. 11 (top left)—Blowhole distribution in high-carbon ingots, bottom and top poured, respectively, computed freezing-front positions are shown also.  
a—left. b—right.

Fig. 12 (bottom left)—Section of the top-poured ingot at location indicated in Fig. 11b.

Table II. Composition of High-Carbon Ingots

| Heat   | Composition, Pct |    |      |       |       | Casting Method |
|--------|------------------|----|------|-------|-------|----------------|
|        | C                | Si | Mn   | P     | S     |                |
| M 3110 | 0.40             |    | 0.58 | 0.061 | 0.039 | top-poured     |
| M 3090 | 0.37             |    | 0.58 | 0.014 | 0.037 | bottom-poured  |

top-poured, and about 6 min for the bottom-poured ingot.

Blowhole distribution in both ingots is shown in Fig. 11, which also gives freezing front positions for a series of intervals after casting commenced. These positions were calculated from the formula  $D = 0.87\sqrt{t}$ , where  $D$  is thickness in in., and  $t$  time in min. The top-poured ingot has more blowholes in the rim zone than has the bottom-poured one. Both show cauliflower tops.

Fig. 12 shows the primary structure of a selected part of the section of the top-poured ingot, its position being indicated in Fig. 11. Corresponding freezing front lines are plotted in Fig. 13. The skin portion (zone I), about 0.15 in. thick, shows numerous "blowhole seats" too small to be visible in reproduction. Next inward is zone II, extending to a depth of about 0.6 in., showing dendritic structure and containing some large blowholes but no blowhole seats. The next zone, III, also contains blowholes but has a globular primary structure. A reconstruction of the freezing sequence would be as follows: Zone I obviously is solid as a result of strong gas evolution, most bubbles being scrubbed off, leaving blowhole seats. Zone II formed under limited gas evolution—rising type—and zone III formed under increasing gas evolution with most of the gas moving away. Upward passage of the bubbles was retarded by projections in the freezing front and suspended small crystals. In this way the marked steep string segregates were formed. Blowhole segregates formed on compression of blowholes with each new gas bubble forming at a higher pressure than a preceding one nearer the surface.

The successive formation of three distinct zones can be explained if the variation in ferrostatic pressure during the rapid casting is considered. While zone I froze, the pressure was low and gas evolved freely. As the steel level rose and pressure with it, less and less gas was liberated (zone II). After casting was finished, and under the following period of stationary ferrostatic pressure, gas evolution increased as segregation mounted. This explanation appears to agree with the position of the freezing front lines plotted in Fig. 13.

Most of the oblong blowholes in the rim zone of this ingot, consequently, are believed to be of the kind typical of rising steel. In the top fifth of the ingot—below the top part that has risen—there are only a few blowholes in the rim zone, probably owing to a lower ferrostatic pressure and hence greater gas evolution.

A similar selected part of the bottom-cast ingot is shown in Figs. 14 and 15. Here also three zones may be distinguished. On account of the slow casting—6 min—zone I, with numerous blowhole seats, disturbed dendritic structure, and few blowholes indicating strong gas evolution, is about 1 in. thick. Its inner boundary may be calculated to correspond with a moment  $2\frac{1}{2}$  min after casting commenced and with a steel level almost half way up. Zone II extends to about 2.5 in. from the surface corresponding to 8 min after zero casting time. During this period, the ferrostatic pressure was sufficient to

Fig. 13—Freezing-front lines for section shown in Fig. 12.

Fig. 14—Section of the bottom-poured ingot at location indicated in Fig. 11a.

Fig. 15—Freezing front lines for section shown in Fig. 14.

Fig. 16—Carbon, phosphorus, and sulphur variation in the high-carbon ingots.

check gas evolution, to such an extent that part of the gas remained as large blowholes and part came off, leaving large blowhole seats. Reasoning similar to that given for the top-cast ingot applies to zone III. During this period, when the top crust was not yet strong enough, liquid penetrated it and formed a top part above the crust. A considerable volume of blowholes must have formed simultaneously to account for this phenomenon. These holes were later largely compressed when new blowholes formed in the core. In this way the inner boundary of zone III was moved outward.

Analyses of drilled samples taken from different levels in the two ingots are given in Fig. 16. The low values found in the outer part of the rim zone are evidence of strong gas evolution and movement. In the top-cast ingot, the phosphorus and sulphur contents at the lower levels show a maximum within zone II, in agreement with the postulated checked gas evolution; otherwise, the distribution of elements is similar in the two ingots. As a result of sedimentation segregation, the core shows low values in the bottom portion, and high values in the top portion. Certain peaks within the core are probably due to blowhole segregates.

*Ingots Made in Surahammar:* One 12 in. top-cast ingot made in the acid open-hearth furnace was examined. It contained: 0.38 pct C, 0.03 pct Si, 0.46 pct Mn, 0.34 pct P, and 0.018 pct S. Ferromanganese was added in the furnace, but no aluminum. Casting lasted less than 1 min. Gas evolution was uniform and top level did not change during rimming. Eight to ten minutes after casting the ingot was capped. The rim was then 4 in. wide.

Fig. 17 shows the blowhole distribution. Some large rim holes appear in the lower half of the ingot and in its top portion. In the region where rim holes are absent there are intermediate blowholes. The core is solid, except for a few large blowholes around and at the freezing center in the top.

The primary structure of a section from half height is seen in Fig. 18. Surface zone I, about 1 in. thick, corresponding with a time of formation of 1.3 min, contains few blowholes and has a disturbed finely dendritic structure with occasional blowhole seats. Obviously it froze under fairly strong gas evolution. Next is solid zone II, with globular structure and with blowhole seats here and there. It is terminated at a depth of about 2.5 in. by some intermediate blowholes. This depth seems to correspond to the moment of capping. The transition to the core zone with its globular structure is otherwise smooth.

This ingot is somewhat more solid than the two already described of a similar composition, indicating good rimming action. Possibly the casting temperature was low, whereby freezing was accelerated

Fig. 17 (right) — Blowhole distribution in a high-carbon acid open-hearth ingot.

and the amount of gas liberated per unit time was greater. Why rim holes formed in the upper part where gas evolution and movement during rimming should have been strong is not clear.

The high-carbon rimming steel ingots examined differ in some respects from rimming steel ingots with 0.055 to 0.21 pct C examined earlier.<sup>1</sup> Increasing carbon content increases the development by etching of primary dendritic structure in the surface zone. Further, there is, in the high-carbon ingots, a tendency for a globular structure to develop fairly early during the formation of the rim zone. Gas bubbles appear to detach themselves less easily and, during rising, are more often detained than in lower carbon ingots. To some extent, the lesser amount of gas set free may be responsible. On the other hand, the widening of the freezing range caused by the higher carbon content may be of importance. The degree of segregation with respect to the distribution of phosphorus, sulphur, etc., between solid and liquid probably increases with the carbon content; thus, the marked contrast in the etched structure is explained. Further, the depth of the freezing zone during growth of the rim zone is increased for the same reason; in other words, the freezing front is less smooth, with the effect on the bubbles referred to. The uneven front should also tend to retard the movement of the liquid.

Globular primary structure indicates the presence of numerous small crystals in the liquid. Possibly protruding points of the crystals growing from the wall are to some extent broken off by the moving liquid. The main cause of the globular structure, however, is believed to be connected with the stronger segregation in the liquid steel ahead of the freezing front and the consequent retardation of the growth of the rim zone. The temperature of this segregated liquid corresponds to its liquidus and is therefore lower than the liquidus for the main melt immediately inside it which is only slightly contaminated by mother liquor. Thus the latter will be subjected to turbulence below its liquidus temperature; in other words, the conditions for precipitation of numerous crystals and formation of a globular, nondendritic structure are realized. High contents of other elements lowering the freezing point may be assumed to have a similar effect.

The Degerfors steel showed a rising tendency. As ingot M3090 shows, slow casting is likely to counteract this tendency and to produce a fairly thick solid surface zone otherwise typical of normal rimming steel. As stated, the Surahammar ingot had a fairly solid surface zone, despite rapid casting. It may be concluded therefore that a carbon content of 0.40 pct does not preclude good rimming.

### Large Inclusions in Rimming Steel Ingot

In rimming steel ingots large round or rounded nonmetallic inclusions are commonly present. Although their matrix is transparent they usually contain particles of opaque (Fe, Mn)O and MnS or FeS. The matrix, obviously, is a silicate poor in silica. Such inclusions may be seen with a binocular microscope at a magnification of 20 to 30 diam. Their color may be yellowish, brownish, or gray. Some ingots from the earlier investigation<sup>1</sup> were examined in this way; all inclusions above 0.05 mm being measured and counted, and their distribution in the ingot section determined. The results are given in Tables III and IV.

The results may be summarized as follows:

Fig. 18—Structure of a half-height section of the ingot shown in Fig. 17.

1. The core contains a greater amount of large inclusions than the rim zone.
2. In the rim zone, the amount possibly increases towards the bottom.
3. In the core there is a definite such tendency.
4. The amount is not necessarily governed by the carbon content of the steel.

The fact that there are more large inclusions in the core than in the rim zone, although the former, for the carbon contents in question, has a lower oxygen content, probably results from its coarser primary structure in the sense of more open spacing of the small scale segregates. The number of inclusions of the same kind smaller than 0.05 mm would accordingly be less in the core. The accumulation of large inclusions in the lower portion of the core is probably connected with the sedimentation of the metal crystals, a well-known feature in killed-steel ingots also.

### Extent of Continuity in Rim Channels

In an ingot of normal rimming steel, at least the upper half, the rim zone is free from rim holes; however this portion probably always contains long narrow, roughly horizontal pores; so-called rim channels. These, like the rim holes, are assumed to be remnants of gas bubbles evolved at the freezing front during rimming. The movement of the liquid metal in the upper part of the ingot being very rapid, only small portions of the bubbles manage to remain as holes.<sup>1</sup> It appeared to be of interest to establish the extent of continuity existing within each channel.

This was done by cutting sections from a 2-ton

Fig. 19—Location of test samples. Dimensions are in mm.

ingot made at Domnarfvet, containing 0.08 pct C, 0.20 pct Mn, 0.017 pct P, and 0.029 pct S; their locations are shown in Fig. 19. The outer surface was machined to a depth of 0.28 in., corresponding to several times the depth ordinarily lost by burning during heating. The samples were prepared further by installation of a threaded cap, as shown in Fig. 20. Tests were conducted by filling the top depression with water, then putting the space between cap and sample under 8-atm air pressure. Metal was then bored out and the test repeated until the test piece was no longer pressure tight. Boring was done from outside in, in one instance, and inside out in the other. In the first instance, the sample remained pressure tight for a distance from the outside surface of 1¼ in., whereas in boring from the inside surface, a depth of 2⅞ in. was reached before there was leakage. It may be concluded, therefore, that the rim channels were discontinuous to a depth of 1¼ in. from the surface, whereas there was continuity from this depth to the intermediate blowhole zone. Similar results were obtained on samples from a 0.25 pct C ingot.

Table III. Inclusion Distribution in Bottom-Cast Ingots Made at Kallinge

| Sample No. | Average Distance from Bottom, In. | Ingot A, 0.08 Pct C, Vol Pct x 10 <sup>3</sup> |      | Ingot B, 0.09 Pct C, Vol Pct x 10 <sup>3</sup> |      |

Fig. 20—Details of assembly for continuity test.

### Summary

1. When rimming steel is allowed to solidify under pressure the evolution of gas during solidification is reduced, the more the higher the pressure. Accordingly, blowhole distribution and primary structure are governed by the pressure. When the pressure exceeds a certain minimum, no gas evolution takes place and the structure shows the characteristics of a killed steel.

2. On experimenting with a steel with 0.12 pct C (determined on unkilld sample) and 0.48 pct Mn, an additional air pressure of 10 to 15 atm was sufficient for preventing all gas evolution during solidification. Under an additional pressure of 6.5 atm (0.07 pct C, 0.24 pct Mn) a semikilled ingot was obtained and under 3 to 4 atm (0.08 pct C, 0.33 pct Mn) a rising ingot.

3. The application of a lid, with a casting orifice, appeared to reduce gas evolution during rimming somewhat. Hence the steel may rise during this period. A similar effect probably was produced by a refractory lining at the top of the mold.

4. Rimming steel with about 0.40 pct C differs from such steel of lower carbon contents in that a good rimming action seems more difficult to produce, although not impossible. The inner part of the rim zone tends to develop a globular freezing structure. On slow casting, the outer part of that zone contains fewer blowholes than on rapid casting.

5. Large nonmetallic inclusions in rimming steel ingots with 0.08 to 0.21 pct C appear in larger amount in the core than in the rimming zone and in larger amount in the lower than in the upper part of the core.

6. Rim channels in rimming steel ingots in two cases were found to show continuity from a depth beneath the ingot surface of about 30 mm to the intermediate blowholes but not outside of the 30 mm depth.

The experiments with rimming steel ingots solidified under pressure and the tests to establish the extent of continuity were made at the Domnarfvet Steel Works, the ingots of high-carbon content were made at the Degerfors and the Surahammar steel works. The investigations of structure and inclusions were carried out at the Royal Institute of Technology, Stockholm. For valuable assistance with the latter tasks the authors are indebted to Raymond Nordstrom.

Until his untimely death in 1944, G. Phragmén was very active in the investigations. Behind the results reported stands the whole committee, which since 1940 has included H. Gillo and M. Wiberg.

# Vanadium-Oxygen Equilibrium in Liquid Iron

by John Chipman and Minu N. Dastur

This paper presents equilibrium data on the reaction of water vapor with vanadium dissolved in liquid iron at 1600°C. The thermodynamic behavior of vanadium and oxygen when present together in the melt is discussed. A deoxidation diagram is presented which shows the concentrations and activities of vanadium and oxygen in equilibrium with  $V_2O_3$  or  $FeV_2O_4$ .

**S**TUDIES of the chemical behavior of oxygen dissolved in pure liquid iron<sup>1-3</sup> have served to determine with a fair degree of accuracy the thermodynamic properties of this binary solution. The practical problems of steelmaking, however, involve not the simple binary but ternary and more complex solutions. Only a beginning has been made toward understanding the behavior of such systems. The silicon-manganese-oxygen relationship was studied long ago by Körber and Oelsen<sup>4</sup> and more recently by Hilty and Crafts.<sup>5</sup> The carbon-oxygen reaction was investigated by Vacher and Hamilton<sup>6</sup> and by Marshall and Chipman.<sup>7</sup> A number of deoxidizing reactions have been studied empirically<sup>8-10</sup> with the object of determining the appropriate "deoxidation constants."

The work of Chen and Chipman<sup>11</sup> afforded a clear-cut view of the effect of the alloy element, chromium, on the thermodynamic activity of oxygen in liquid ternary solutions. These investigators determined the oxygen content of experimental melts which had been brought into equilibrium with a controlled atmosphere of hydrogen and water vapor and were able to show that the presence of chromium decreases the activity coefficient of oxygen. They determined also the conditions under which the two deoxidation products,  $Cr_2O_3$  and  $FeCr_2O_4$ , were formed and showed that the activity of residual oxygen is considerably less than its percentage.

It was the object of this investigation to apply a similar method to the study of molten alloys of iron, vanadium, and oxygen. Vanadium was once considered a moderately potent deoxidizer, but this is now known to be erroneous, in the light of its behavior in steelmaking practice. Its reaction with oxygen retains a certain amount of practical interest in that a high percentage of one element places a limit on the amount of the other that can be retained. As a deoxidizer it will be shown that vanadium lies between chromium and silicon.

## Experimental Method

The apparatus was that used by the authors<sup>3</sup> in their study of the equilibrium in the reaction:

Crucibles of Norton alundum or of pure alumina

were used. The latter were made in this laboratory and were of high strength and low porosity. Under conditions of use they imparted no significant amount of aluminum (less than 0.01 pct) to the bath. Temperature measurements were made with the optical equipment and calibration chart of Dastur and Gokcen.<sup>12</sup>

The charge was made up of calculated amounts of ferrovanadium (20 pct V) and clean electrolytic iron totaling approximately 70 g. The first few heats were made in alumina crucibles with an insufficient amount of vanadium so that no oxide of vanadium would be precipitated under the particular gas composition. All the heats were made at 1600°C under a high preheat and with four parts of argon to one part of hydrogen in the gas mixture to prevent thermal diffusion. The rate of gas flow was maintained constant at 250 to 300 ml per min of hydrogen. The time for each heat was three quarters of an hour after the melt had melted and attained the required temperature (1600°C).

The water-vapor content of the entrant gas mixture was gradually raised in succeeding heats, keeping the vanadium content of the melt constant. This was controlled by manipulation of saturator temperature. A point was reached when for a given  $H_2O:H_2$  ratio some of the dissolved vanadium was oxidized and appeared as a thin, bright oxide film on top of the melt. By raising the temperature of the melt it was possible to dissolve the oxide film which reappeared as soon as it was cooled down to 1600°C. The temperature readings taken on the oxide film were consistently higher by 80° to 85°C as observed by the optical pyrometer. The heat was allowed to come to equilibrium under a partial covering of this oxide film.

At the end of the run the power and preheater were shut off and the crucible containing the melt was lowered down into the cooler region in the furnace. This method of quenching proved quite

rium runs for saturated vanadium-iron melts, are marked with an asterisk in Table I.

### Identification of Oxide Phases

The oxide films formed on the surfaces of five typical ingots were examined by X-ray methods. The amount of film material was insufficient for use as a powder sample. Films were too thin to register a pattern by the back-reflection method. The forward-reflection Hull method was therefore employed using a pinhole camera. The X-ray beam from a chromium target was made to graze the specimen at a very acute angle so as to enable it to traverse as great a thickness of the oxide layer as possible.

The results for two ingots of high- and low-vanadium content are shown in Fig. 1 where the differences in pattern are clearly evident. Measurements of the observed patterns recorded in Table II agreed as well as could be expected for this method with the known patterns of  $V_2O_5$  and  $FeV_2O_4$ . The former was found on ingots containing more than 0.35 pct V. The latter, which is the spinel identified by Mathewson, Spire, and Samans,<sup>18</sup> was found on two ingots of 0.10 pct V.

Identification of the very small nonmetallic inclusions found in the ingots by microscopic examination was considerably less certain than the X-ray identification of the oxide films. Inclusions in low-vanadium ingots were of duplex structure containing wüstite and a dark phase, presumably the spinel. At higher vanadium levels wüstite disappeared and one or sometimes two dark phases were visible. In view of the inconclusive nature of this evidence, the identification rests solely upon the X-ray evidence.

effective, the solidification time never exceeding 10 sec.

### Results

Altogether 30 heats were made, of which 12 were unsaturated vanadium-iron alloy melts and 3 were discarded due to failure of some part of the apparatus or the breaking of a crucible. The equilib-

### Activity of Oxygen

It has been shown<sup>8</sup> that the value of  $K_1$  (eq 1) for pure iron-oxygen alloys at 1600°C is 3.95. In this case the activity of oxygen,  $a_o$ , is equal to its percentage by weight in the melt.<sup>1</sup> In the presence of vanadium the activity is found to be somewhat diminished; it becomes necessary, therefore, to in-

\* Iron-vanadium alloys saturated with oxygen.

Fig. 2 (above)—Effect of vanadium on the activity coefficient of oxygen,  $f_o$ .

Fig. 3 (right)—Equilibrium in the reaction of water vapor with vanadium in liquid iron at 1600°C. Above the break, the oxide is  $V_2O_3$ ; below the break,  $FeO \cdot V_2O_3$ .

introduce an activity coefficient,  $f_o$ , defined by the equation:

$$f_o = a_o / \% O$$

The equilibrium constant of eq 1 becomes:

$$K_1 = \frac{p_{H_2O}}{p_{H_2} \cdot f_o \cdot \% O} \quad [1a]$$

Using the value  $K_1 = 3.95$ , values of  $f_o$  are readily obtained for each heat of Table I. These are shown in Fig. 2 where the logarithm of  $f_o$  is plotted against the percentage of vanadium. The straight line represents adequately both saturated and unsaturated heats. The effect of vanadium on the activity coefficient of oxygen is considerably larger than that reported for chromium.<sup>11</sup>

### Reaction of Vanadium with Water Vapor

If we assume that either of two solid phases occurred in the films found on the saturated heats, and that these have compositions corresponding to the structures indicated by X-ray diffraction, the equations for the two equilibria may be written:

It may be assumed that the solution is dilute enough to conform to Henry's law and hence that the activity of vanadium may, by definition, be placed equal to its percentage by weight.

The data on all saturated heats are plotted in Fig. 3. A logarithmic scale is used and two lines are drawn having slopes of 3:2 and 4:2 corresponding to the requirements of eqs 2 and 3, respectively. These two lines fit the data fairly well except for

some deviation at the highest vanadium level. This deviation may be attributed to departure from Henry's law or possibly to the appearance of a third (lower) oxide phase, but there is no evidence of either and it may be regarded as the result of experimental inaccuracy. The two lines intersect at 0.17 pct V at which composition the two oxide phases coexist in equilibrium with the melt at 1600°C.

The equilibrium constants and free energies of reactions 2 and 3 corresponding to the two lines of Fig. 3 are, at 1600°C:

$$K_2 = 1.1 \times 10^{-4}; \Delta F^\circ_2 = +34,000 \text{ cal} \quad [2a]$$

$$K_3 = 1.7 \times 10^{-5}; \Delta F^\circ_3 = +40,800 \text{ cal} \quad [3a]$$

The free-energy change in the deoxidation of steel by vanadium is obtained by combining these two equations with eq 1 of the previous paper which is:

This yields the following values for the two free-energy changes at 1600°C:

The experimental data are insufficient to express the free energy as a function of temperature. Approximate equations covering this relationship will be derived in a later section.

### Comparison with Low-Temperature Data

The free energy of  $V_2O_3$  is obtained from its heat of formation at 25°C which, according to Siemonsen and Ulich,<sup>14</sup> is -296 kcal, and entropy values given by Kelley.<sup>15</sup> The heat capacities of V and  $V_2O_3$  in the range 25° to 1600°C are taken respectively from Jaeger and Veenstra<sup>16</sup> and Cook.<sup>17</sup> The result, for

Fig. 4—Deoxidation diagram for vanadium in steel at 1600°C. Lower line shows oxygen activity; upper line, oxygen percentage in equilibrium with solid  $V_2O_5$  or  $FeV_2O_4$ .

a temperature range of 1400° to 1700°C, may be expressed in the simple form:

For comparison with our experimentally determined free energy we must subtract from this the free energy of solution of 3/2 mol of oxygen in liquid iron. From our previous paper<sup>3</sup> this is:

The result is:

The next step in the computation requires the free energy of solution of solid vanadium in the dilute solution corresponding to the experimental range. This information is lacking altogether. Instead of assuming that the solution is ideal, the comparison of calculated and observed free energies will be completed by computing the deviation of the solution from Raoult's law. For this purpose eq 5 is subtracted from 9 to obtain:

Now if vanadium formed an ideal solution in iron, this free-energy change could be computed by well-known methods which are adequately discussed in "Basic Open Hearth Steelmaking."<sup>18</sup> The heat of fusion of vanadium has not been measured but, since temperatures not far below its melting point are the concern here, the error introduced by this uncertainty is entirely negligible. Taking the entropy of fusion as 2.1 cal per degree mol, the free-energy change for eq 10 is computed as -16,700 cal. The discrepancy of 8000 cal is greater than the probable errors of the subsidiary data, although earlier values for the heat of formation of  $V_2O_5$  differed by 34,000 cal from that used here. It will be assumed that the 8000 cal represents the actual deviation from Raoult's law of the ideal solution.

The activity coefficient of vanadium in the dilute solution, defined here as the ratio of its activity to its mol fraction, is computed by equating the deviation -8000 cal to  $RT \ln \gamma^\circ$  from which:

$$\gamma^\circ = 0.12 \quad [11]$$

To apply this to temperatures other than 1600°, the deviation from Raoult's law will be attributed to a heat of solution of vanadium in iron, i.e., it will be assumed that the solution is "regular" and that the

deviation is not in the entropy. The resultant equation is:

$$V(s) = \underline{V}; \Delta F^\circ = -3900 - 11.1T \quad [12]$$

It should be stressed that eqs 10, 11, and 12 are approximations which depend upon thermochemical data of unproved accuracy. An error of 5 kcal in the heat of formation of  $V_2O_5$  would correspond to a factor of 2 in the value of  $\gamma^\circ$ . It seems safe to conclude that the vanadium-iron solution exhibits negative deviation from Raoult's law and that  $\gamma^\circ$  is probably less than 0.25.

### Effect of Temperature on Equilibria

Since all the experimental data were obtained at 1600°C, the effect of temperature can be learned only through calculations. The foregoing equations provide the basis for a very reasonable approximation. Combination of eqs 9 and 12 gives:

Available data are insufficient for a similar calculation of the equilibrium involving the spinel.

### Deoxidation with Vanadium

Although vanadium is not used as a deoxidizer in practice, its behavior in the deoxidation reaction illustrates a principle which is applicable to all such reactions. It has been shown that the activity coefficient of oxygen is strongly decreased by the presence of vanadium. The deoxidation constant corresponding to equilibrium in eq 13 must be expressed in terms of the activities of vanadium and oxygen, thus:

$$K = a_V^2 \cdot a_O^3 = [f_V \cdot \% V]^2 [f_O \cdot \% O]^3 \quad [13a]$$

Values of  $K$  at 1500°, 1600° and 1700°C are  $1.0 \times 10^{-7}$ ,  $1.8 \times 10^{-6}$  and  $2.6 \times 10^{-5}$ .

In Fig. 4 the lower line represents the activity of oxygen corresponding to any concentration of vanadium for metal in equilibrium with  $V_2O_5$  at 1600°C. Since the oxygen concentration is small its effect on the activity of vanadium is considered negligible.

The upper line of Fig. 4 shows the experimentally determined oxygen content of the same metal. The two portions of each curve intersecting at 0.17 pct V correspond to equilibrium with  $V_2O_5$  above and  $FeV_2O_4$  below the intersection.

This deoxidation diagram proves to be somewhat more complex than its earlier prototypes. At the same time it contains a greater amount of information. It displays the two-fold effect of a deoxidizing element in reducing not only the solubility of oxygen in the melt but also the activity of that oxygen which remains. The question of whether, in a given case, the upper or the lower line is used must depend upon the information desired, that is, how much oxygen is in solution in the metal or how that oxygen behaves.

### Summary

An experimental study has been made in which molten iron-vanadium alloys containing 0.03 to 1.3 pct V were brought into equilibrium with controlled atmospheres of water vapor and hydrogen at 1600°C. When the gas mixture is sufficiently oxidizing, an oxide film forms on the metal surface. This was identified as  $V_2O_5$  on melts containing 0.36 pct or more, and as the spinel  $FeV_2O_4$  on melts containing 0.10 pct V.

From the oxygen content of the melts and the

known value of  $K_1 = p_{H_2O}/(p_{H_2} \cdot a_O)$  in pure iron, the activity of oxygen in the alloy was obtained. Vanadium decreases the activity coefficient of oxygen, the logarithm of the latter being proportional to the concentration of vanadium.

A deoxidation diagram is presented in which two lines show respectively the percentage and the activity of oxygen in the alloy. Each line shows a change in slope at approximately 0.17 pct V. Above this concentration the solid phase is  $V_2O_5$ , and below it is  $FeV_2O_4$ .

#### Technical Note

### "Oriented Growth" in Primary Recrystallization

by Joseph J. Becker

RECENTLY the "oriented growth" hypothesis of recrystallization textures has been receiving considerable attention. According to this view, "when ever a new generation of grains is growing in a highly oriented matrix . . . one may assume . . . that from among available nuclei of a great variety of orientations those with suitable orientation relationship with respect to the matrix have by far the highest rate of growth (oriented growth) and will, therefore, predominate."<sup>1</sup> This statement includes primary recrystallization of single crystals and of polycrystalline materials showing strong deformation textures as particular cases. While the phenomenon of oriented growth undoubtedly does operate, and may be of importance in coarsening or secondary recrystallization, the writer feels that its extension to primary recrystallization is a different matter. Several aspects of this phenomenon may be pointed out which are difficult to rationalize on the basis of oriented growth.

In recrystallizing deformed single crystals of alpha brass, Maddin, Mathewson, and Hibbard<sup>2</sup> found that the twin composition planes of the recrystallized grains were parallel to the three operative slip planes they observed, and not to the fourth octahedral plane. The writer's current work seems to indicate further that when only one or two slip systems can be seen to operate, the recrystallized grains are aligned only with those slip planes actually observed. This behavior could hardly be accounted for by oriented growth, because on the latter basis the recrystallized texture of a deformed single crystal should certainly have the same symmetry as the crystal itself. Growth rates could not be expected to distinguish between crystallogra-

phically equivalent directions, unless the presence of a visible slip system vastly increases the growth rate in the appropriate direction. This seems unlikely.

These relationships were observed by the writer only when considerable care had been exercised before annealing to etch away the effects of cutting out the centers of tensile specimens with a jeweler's saw and to etch off the ends of compression specimens. When these precautions were not taken, nucleation inevitably appeared to occur at the saw cuts or at the ends, and the resulting orientations never showed a [111] rotation but appeared quite random. The provision of many nuclei of many orientations did not enhance the correlation, but destroyed it.

Recrystallization textures are sometimes strongly dependent on annealing temperature, which would imply that the anisotropy of growth rates is a suddenly varying function of temperature. This might be regarded as unlikely.

Recrystallization textures can be strongly dependent on the degree of deformation. If textures are to be explained by selective growth from among nuclei of all orientations, it is difficult to see how the recrystallization process could have any dependence whatever on the manner or degree of deformation.

It is felt that the above points should be considered before the oriented growth hypothesis is applied to primary recrystallization, with the necessary complete divorce of the mechanism of recrystallization from the details of the deformation process.

# Sintering Practice At Josephtown Smelter

by H. K. Najarian, Karl F. Peterson,  
and Robert E. Lund

**P**RIMARY products of the Josephtown smelter are zinc metal of various grades, lead-free zinc oxide pigments, cadmium metal, and sulphuric acid. Zinc concentrates of domestic and foreign origin are blended and desulphurized at the roaster plant. The equipment includes five, 12-hearth Herreshoff roasters and two modified Trail-type suspension roasters. The sulphur dioxide containing gases from the roasting operation are diverted to a four-unit contact acid plant for the manufacture of sulphuric acid. The roasted calcines are agglomerated by sintering on Dwight-Lloyd-type sintering machines; the sinter is crushed and sized within required limits; and the sized sinter is smelted in vertical shaft-type electrothermic furnaces. Of the 13 electrothermic furnaces of various sizes now in operation, four are designed to produce American process zinc oxide of various specifications; and the remaining nine furnaces are equipped with vacuum-type condensers and produce zinc metal. Papers describing the general smelting practice at Josephtown have been published by AIME.

Since both High Grade zinc metal and lead-free zinc oxide pigments are produced direct from the electrothermic furnaces without need for subsequent refining, the elimination of impurities such as lead and cadmium has to be accomplished during roasting and sintering operations.

To effect the producing of both High Grade and Prime Western zinc products, the roasting and sintering operations are on two separate circuits. A High Grade circuit produces finished sized sinter low in lead, cadmium, etc., for the High Grade furnaces; and the Prime Western circuit produces finished sinter destined for the furnaces producing Prime Western metal.

Sintering at the Josephtown smelter differs in many important respects from the sintering practice in smelters operating horizontal retort zinc furnaces. Requirements of the electrothermic smelting furnaces define the physical characteristics of the sinter, while the chemical composition of the sinter is controlled according to the grade of metal and oxide to be made as final products. Three principal objectives in the sintering process at Josephtown smelter are:

1. To transform the zinc calcine from the roasting operations into a hard, yet porous agglomerate that will not crumble in the smelting furnace.

N. K. NAJARIAN and KARL F. PETERSON, Members AIME, and ROBERT E. LUND, Junior Member AIME, are General Smelter Superintendent, and Superintendent and Assistant Superintendent, respectively, of Sinter and Leaching Plants, St. Joseph Lead Co., Monaca, Pa.

Discussion on this paper, TP 3011D, may be sent (2 copies) to AIME by April 1, 1951. Manuscript, Oct. 16, 1950. St. Louis Meeting, February 1951.

2. Crushing and sizing of the sinter to obtain a proper screen analysis which is normally  $-\frac{3}{4}$  in. down to  $+\frac{1}{4}$  in. particle size.

3. To eliminate, particularly in the High Grade circuit, as much of the impurities such as sulphur, lead, and cadmium as possible.

The sintering plant as originally built in 1930 was equipped with three standard 42 in. x 44 ft Dwight-Lloyd sintering machines. Each machine was equipped with a 15x60 in. sintering corporation fan driven by 150 hp, 900 rpm synchronous motor through a magnetic clutch and capable of delivering 30,000 cfm of air at 15 in. of water and 150°F. Each sintering machine was driven by 7½ hp dc motor with controllers for varying the speed of the machine from 8 to 32 in. per min. The pallets were cast iron and the grates of the herringbone type. The charge was mixed in a 4 ft diam x 8 ft Stehli pugmill and transported by belt conveyor, elevator and tripper conveyor to a small bin over each machine.

Shortly after the start of operations the following changes were found necessary:

1. The herringbone grates which plugged very quickly and were difficult to keep clean were replaced by straight, narrow cast-iron grate bars running at right angles to the travel of the pallets. These grate bars are held in place by a center bar extending across the pallet on the 24 in. dimension and by removable retaining plates which form the sides of the pallets.

2. Mechanical grate knockers were developed in conjunction with new grate bars for continuously and automatically cleaning the grates.

3. As the cast-iron pallets cracked, they were replaced with cast-steel pallets.

In 1938, the capacity of the sinter plant was increased with the installation of two 42 in. x 22 ft machines which were brought from the company's Herculeaneum lead smelter. With a circulating load of some 250 to 300 pct, production of finished sinter on the 42 in. x 44 ft machines at this time amounted to about three tons of sized sinter per machine hour.

In 1945, one of the 42 in. x 22 ft machines was replaced by a 60 in. x 44 ft machine of our own design.

In 1948, as part of the plant-wide expansion program, the sinter plant not only was expanded but also divided into two separate plants; namely, Prime Western and High Grade circuits. The sinter destined for furnaces producing Prime Western zinc metal is made in a new plant comprising two 60 in. x 44 ft Dwight-Lloyd-type sintering machines, each having a 45,000 cfm Sturtevant fan at 18 in. water static pressure and served by an 8 ft diam x 12 ft long rotary charge pelletizer and auxiliary crushing and sizing equipment. The sinter destined for furnaces producing High Grade zinc metal and zinc oxide pigments is produced in the old sinter plant which was expanded to accommodate four of the 60 in. x 44 ft sintering machines, replacing the old sintering units. In the High Grade sinter circuit, two units of the 60 in. x 44 ft machines are used as preliminary soft sinter machines; and the remaining two units of the 60 in. x 44 ft machines are used to make finished hard sinter.

## Purification Theory

Partial elimination of lead and cadmium in the sintering of zinc ores is common knowledge. However, by some manipulation and by taking advantage of the double circuit, it is possible to make zinc sinter which is nearly free of contaminators. Lead

and cadmium, both being more easily reduced with carbon than zinc and being quite volatile in the sulphide form, are driven ahead of the intensely hot burning zone in the sinter cake. On the soft sinter machines, the charge is quite refractory; therefore little slagging takes place during the burning of the charge. The top part of the bed is more nearly free of impurities than the bottom due to condensation of lead and cadmium compounds at the grate area.

It is important to have an open fast-burning charge and a high fusion point charge in order to get good elimination. Equally as important is a charge with the proper amount of fuel and moisture. Our experience has shown 4 to 4.6 pct coke is necessary with a calcine sulphur of from 1 to 3 pct.

To produce a sinter of requisite hardness, it is necessary to add to the charge enough silica sand to obtain 8 to 9 pct  $\text{SiO}_2$  in the finished sized sinter. However, addition of this silica to the sinter mix inhibits the elimination of lead and cadmium during sintering. Therefore the low-lead calcines brought in to this High Grade sinter circuit from the roaster plant are given a preliminary soft sintering without the addition of silica sand. This results in the elimination of 80 pct of the lead and some 90 pct of the cadmium and sulphur.

The product of the soft sintering step is resintered with the addition of silica sand and some intermediate products to produce the finished, hard sized sinter required for the High Grade furnaces.

### Prime Western Sintering Circuit

The feed for the Prime Western sintering circuit comprises very fine suspension roaster calcines, —3/16 in. residues from the Prime Western furnaces, and dust collected in the Dracco collector from sinter, coke, residue, and furnace plants.

A typical charge going to the Prime Western machines is, in pounds per minute: calcine, 250; Dracco dust, 200; residue fines, 100; coke (—8 mesh), 50; sand (about 30 mesh), 8; and circulating return sinter, 1000.

All of these charge components are stored in steel storage feeder bins of adequate capacity. From the storage bins, calcines and Dracco dust are fed by screw feeders and the remaining components are fed by belt-type feeders on to a collecting screw conveyor which delivers it to an elevator discharging directly into a rotating pelletizer. The mixed charge contains about 4.4 pct coke fuel, part of which comes in through the Dracco dust and the residue fines. The residue fines in the charge are that portion of the reclaimed high-zinc furnace residues which passes through a 3/16 in. screen opening. The charge material is mixed quite thoroughly while the material is being conveyed through the screw conveyors and the elevator to the pelletizer. This unit is 8 ft in diam and 12 in. long. It rolls on two large steel tires and is driven by a 15 hp motor directly connected to a speed reducer, which is in turn connected to an 18 T-8 in. F spur gear driving the ring gear that encircles the drum. The discharge end is completely enclosed and vented to a sinter machine wind box.

In the pelletizer, the charge is moistened with water or dilute zinc sulphate solution by means of a pipe spray so designed that the solution is sprayed on the material during its entire passage through the pelletizer. The wetting solution is a byproduct of the leaching operations plus run-off water from Cottrell conditioning chambers. It has been found that a small amount of zinc sulphate in the spray

water in the pelletizer promotes adherence of fine particles to the larger granular particles, resulting in more or less rounded pellets of various sizes. This, experience shows, makes an ideal feed for sintering.

The mix in the pelletizer tends to stick and build up on the inside of the pelletizing drum. A ribbon screw, rotating independently of the pelletizer and contacting the inside periphery of the pelletizer drum near the horizontal center line, continuously cleans the inside of the drum. The drum rotates at about 17 rpm and the cleaner screw at about 80 rpm, both in the same direction.

The pelletized feed is discharged onto a rotating table where two plows split the feed and transfer it to belt conveyors which in turn carry it to the feed end of the sintering machines. The charge drops onto the grates through a rubber-covered swing spout which distributes the charge across the grates in an even fashion, allowing the coarser particles to roll onto the bare surface of the grates. The sintering machine speeds are maintained so that the charge is kept as low as possible behind the spreader plate so as to maintain a fluffy charge. The density at this point is about 130 lb per cu ft.

The charge is ignited by a gas-fired muffle using byproduct CO from the zinc condensers as fuel. Sintering machine speeds vary between 12 and 16 in. per min depending on rapidity of burning. The draft on the wind boxes will average 13 in. of water, varying from as low as 9 in. to as high as 18 in. depending on the condition of the charge. A dense, poorly pelletized charge will be slow burning and have a high wind-box draft. The operator changes the charge as conditions dictate. If for some reason the charge becomes tight and will not burn as rapidly as mix is being fed onto the machines, the condition soon is aggravated by unburned mix appearing in the return sinter. To remedy this, the operator cuts the volume of new charge in the mix; that is, calcine, residue fines, and Dracco dust so that the machine can be run more slowly and allow more time for burning. Proper moisture in the mix is very important to good charge preparation. Our experience has been that 9½ to 11 pct moisture, depending somewhat on the fineness of the material and the ratio of fines to coarse, gives good results. The charge is approximately 97 pct —¼ in. and 35 pct —200 mesh. Charge thickness on grates is carried at approximately 11 in.

A 35 to 40 pct —200 mesh material in the mix has been found to be essential for obtaining a good pelletized charge. Our experience has shown that a pelletized charge comprising rounded granules permits freer passage of gases through the sinter bed and is far superior to a charge of angular particles of various sizes with fines filling the interstices.

The sinter cake as discharged from the machines usually shows a small red hot zone in the lower part of the bed. The cake is broken into some one half dozen pieces as it drops 8 ft onto a 36 in. wide pan conveyor. The pan conveyor carries the sinter to a 24x42 in. toothed slugger rolls which crushes the chunks to —3 in. Sizing is accomplished by first screening the product of the rolls over a rotating trommel having ¾ in. openings. The oversize from the trommel is crushed again in a smooth-faced 36 in. diam x 16 in. face rolls set ⅝ to ¾ in. apart. Roll product is returned to the trommel and a large circulating load is maintained in order that a minimum of fines is produced. The —¼ in. return sinter is separated by screening through a trommel having

Fig. 1—Sinter circuits of Zinc Smelter Division.

$\frac{1}{4} \times \frac{3}{4}$  in. slotted openings. The oversize of this screen is again screened over a  $\frac{7}{16}$  in. screen to make two finished products which are blended to give a uniform sinter size.

The sizing of the sinter feed to the furnaces is very important for proper charge distribution in the furnaces. A typical screen analysis of this sized sinter is as follows:  $-\frac{3}{4} + \frac{1}{2}$  particle size, 35 pct;  $-\frac{1}{2} + \frac{3}{8}$ , 20;  $-\frac{3}{8} + \frac{1}{4}$ , 32; and  $-\frac{1}{4}$ , 8. A typical chemical composition is: Zn, 55.0 pct; Pb, 0.65; S, 0.2; Cd, 0.01; Fe, 10.0;  $\text{SiO}_2$ , 8.7; and MgO and CaO, 1.2.

### High Grade Sintering Circuit

Sintering in the High Grade circuit is in two separate steps. Low-lead calcine from the roasting plant is sintered first without the addition of silica sand to the charge. The resulting product is a soft, easily crushed sinter of high purity. The lead content is 0.005 pct or less, the cadmium content is 0.001 pct or less, and the sulphur content is 0.1 pct. The top half of the soft sinter cake containing the least amount of impurities is removed by means of a rotary slicer, mixed with silica sand, residues from furnaces using High Grade sinter, coke and return fines and sintered a second time to produce the hard, sized sinter which constitutes the feed to the High Grade metal and oxide furnaces.

Of four units of 60 in. x 44 ft Dwight-Lloyd sintering machines in the High Grade circuit, two are used for the soft sintering step and the other two for the hard sintering step.

### Soft and Hard Sintering

A typical charge mix for soft sintering is: low-lead calcines (about 0.05 pct Pb), 400 lb per min; return sinter (crushed), 1000 lb per min; and coke ( $-8$  mesh), 65 lb per min.

An 8 ft x 72 in. Allis Chalmers ball mill is being installed to grind the calcines to insure enough fines (35 to 40 pct  $-200$  mesh) for proper pelletization

of the mix. The return sinter is the bottom portion of the sinter cake crushed to  $-\frac{1}{2}$  in.

The portion of the cake left on the pallet after removing the top is discharged onto a 36-in. pan conveyor which carries it to the 24x42 in. slugger rolls. The product of the slugger rolls, all  $-1$  in., is transferred by means of a 24-in. pan conveyor to a 20 in. diam x 20 in. face smooth rolls set at  $\frac{5}{8}$ -in. opening. The crushed product is conveyed by an elevator and 24-in. pan conveyor to the soft sinter "return fines" bin to be recirculated over the soft sinter machines.

As in the Prime Western sintering circuit, the constituents of the hard sinter mix are fed from respective storage bins by constant volume feeders. This mix is transported to a 6x12 ft rotary drum pelletizer which discharges the pelletized mix onto a rotating table feeder and thence to two sinter machines.

### Sinter Slicers

The slicers on the discharge ends of the soft sinter machines are in the form of a double drum inside of which is a 16 in. screw flight. The outside drum contains cutters tangent to the drum and extending out to be approximately 4 in. from the circumference of the drum. Four of these knives are placed about the circumference of the drum  $90^\circ$  apart and extending the full length of 4 ft 6 in. The cutters are rotated at 20 rpm by means of a 15 hp motorized reducer. Power is transmitted by means of a chain and sprockets. As the drum rotates, it cuts off approximately  $\frac{1}{2}$  in. of charge as deep in the bed as is desired and drops the cuttings into a slot in the inner drum where the screw conveys it to the end and discharges into a chute on one side of the sinter machine. This is the product of these machines. That part which is not taken off by the slicer after burning is crushed to  $-\frac{1}{2}$  in. and recirculated.

The product of the sinter slicer which cuts the top  $\frac{1}{3}$  to  $\frac{1}{2}$  of the soft sinter cake is granular, largely

— $\frac{1}{4}$  in., and contains the least percentage of contaminants such as lead and cadmium. An 8 ft x 72 in. wind-swept Hardinge mill is being installed to grind this material so as to provide some 35 to 40 pct —200 mesh material, the product necessary for good pelletizing of the sinter mix. This ground product, high zinc residues from the High Grade furnaces, coke, silica sand, and return fines, constitute the charge for the High Grade sinter circuit.

A typical charge to High Grade hard sinter circuit sinter machines in pounds per minute is: ground soft sinter, 450; High Grade residue fines, 180; return sinter fines, 1000; silica sand, 10; and coke, 62.

Feeding the various mix constituents, conveying, pelletizing and sintering, crushing and screening are essentially a duplicate of the Prime Western sintering circuit. The product of this plant is a sized hard sinter and is used on all furnaces producing High Grade metal and oxide pigments.

Sizing is carried on in the same manner and with the same standards as were previously mentioned in the discussion of the Prime Western circuit.

Typical chemical analysis of the High Grade sinter is: Zn, 56 pct; Pb, 0.004; S, 0.1; Cd, 0.003; Fe, 10; SiO<sub>2</sub>, 8.7; and CaO and MgO, 1.2.

### Dust Collector

A very important part of the sintering plant is the Dracco dust collector. The unit is made up of 56 individual compartments each containing 80 tapered woolen bags. The bags measure 113 in. long, 6 in. in diam on the top end and 8 in. in diam on the bottom end. Filter rate is from 3.7 to 5.2 cu ft per min per sq ft of bag area. The pressure drop across the bags is from 4 to 5 in. of water. This baghouse takes care of the major part of the dust produced at material transfer points in the sintering, residue, and furnace plants. Suction is supplied by a 12 ft diam Buffalo fan directly connected to a two-speed motor. At low speed, the fan is capable of delivering 200,000 cfm at 8 in. water static pressure and uses a 400 hp, 514 rpm motor. At high speed, the fan rotates at 600 rpm, is driven by a 600 hp motor and will deliver 275,000 cfm at 9½ in. water static pressure. The fan is operated at high speed during the day shift while the furnace plant operations require additional dust removal capacity. Approximately 85,000 cfm is allocated to the sintering plant for dust removal. Approximately 80 tons of dusts are collected each 24 hr and returned to the Prime Western sinter circuit through this baghouse unit.

### Cottrells

An integral appendage to the sintering plant is the Cottrell installation for recovery of fume from the sintering machine gases. Sintering machine gases are discharged from the machine fans into large spray conditioning chambers for humidification prior to entering the Cottrells. Three separate Cottrell precipitators serve the sintering plant. Two precipitators, each rated at 100,000 cfm, receive gases from the hard sinter and soft sinter machines of the High Grade circuit. A precipitator of 150,000 cfm rating was installed to serve the Prime Western circuit with anticipation of expansion to include a third Dwight-Lloyd machine.

Cottrell precipitators were installed by Research Corp. and are of the rod-curtain type. Shell construction is of concrete with a 1-in. ceramic lining. Each precipitator comprises four sections, two in series and two in parallel. Each section in the 100,000

cfm precipitators consists of 21 ducts while the 150,000 cfm precipitator sections contain 27 ducts. Rated gas velocity is approximately 4 fps with a total treatment time of 5 sec. Gas flow is horizontal. High voltage supply for ionization of the gases in each Cottrell is furnished by three transformers of 75,000 v, 25 kva rating with associated mechanical rectifiers.

Proper conditioning of the gases entering the Cottrells is essential for efficient collection. In general terms, the absolute humidity of the gases is maintained as high and the dry bulb temperature as low as physical conditions of the collected dust and corrosion limitations permit. Gases entering the conditioning chambers are cooled to a dry bulb temperature of 130° to 135°F before entering the Cottrells. Absolute humidity is 9 to 11 pct by volume with corresponding relative humidity in the range of 70 pct. Operators maintain optimum precipitator voltage and corona current by transformer tap and rheostat adjustments. All three rectifiers of each Cottrell are operated continuously, one is connected to both inlet sections, and one each to outlet sections. Care is given to cleaning Cottrell electrode members and to proper gas distribution. Precipitators are inspected daily to insure effective rapper operation and clean gas distributing plates.

Dust collected by the Cottrells averages approximately 2 pct of the calcine and soft sinter feed to the sintering machines. This dust is collected in large hoppers under the precipitating chamber. There are two hoppers to each half of the precipitator, each equipped with a 9-in. screw conveyor which feeds into a long, 12-in. collect conveyor. The dust is conveyed to a tank where it is slurried with acid plant scrubber effluent and pumped to the leaching plant for further treatment. Recovery of metallic compounds from the flue gases averages 90 to 95 pct with corresponding exit dust loadings from the Cottrells of about 0.01 grains per cu ft.

A typical analysis of the collected fume from the Prime Western machines is: Zn, 30 pct; Cd, 7; Pb, 9; total S, 10; sulphide S, 5; and Cl, 1.

The conditioning chambers associated with each Cottrell are of acid-proof brick construction and built in two separate units. Each unit averages 27 ft high, is 50 ft deep, and 15 ft wide on the 150,000 cfm Cottrell, 12 ft wide on the 100,000 cfm Cottrells. Average gas velocity is about 3 fps with settling time for suspended solids and water droplets of 17 sec.

Gases entering the conditioning chambers at about 200°F are cooled and humidified by means of high-pressure water sprays to the afore-mentioned conditions. A portion of the run-off water from the conditioning chambers is recirculated after settling of solids in a 30 ft sq settling basin. Warm water makeup is added to enhance vaporization in the conditioning chambers. Bleed-off water, which contains some soluble zinc, is used in the sinter mix.

Water to the conditioner sprays is pressured by a four-stage centrifugal pump operating at 500 psi pressure. High pressure was found desirable in order to obtain effective water vaporization with a reasonable number of sprays.

The material settled in the conditioning chambers, which closely resembles sinter in chemical composition, is cleaned out periodically, allowed to dry by stockpiling a short while, and fed back into the Prime Western sinter mix circuit through a screw feeder. This material represents roughly 1 pct of the calcine and soft sinter feed to the sinter charge.

# The Aging of Sand-Cast Mg-Al-Zn Alloys

by T. E. Leontis and C. E. Nelson

THE properties and casting characteristics of sand-cast Mg-Al-Zn alloys, used commercially in this country and abroad, have been discussed in a number of articles during the past few years.<sup>1-6</sup> In addition, broad surveys of many compositions in the magnesium corner of the Mg-Al-Zn diagram between 0 and 12 pct Al and 0 and 6 pct Zn have been presented by Busk and Marande<sup>7</sup> and by Fox.<sup>8</sup> The purpose of this paper is to furnish a comprehensive survey of the changes in tensile properties, microstructure, and dimensional stability of two magnesium alloys, AZ92A and AZ63A,\* as a function of aging time and temperature after solution heat treatment.

Rates of precipitation in Mg-Al-Zn alloys are slow enough so that a substantially homogeneous, supersaturated solid solution can be maintained even when these alloys are air-cooled from the heat-treating temperature. Consequently, even though it has been demonstrated<sup>9, 10</sup> that significantly higher strengths can be developed in some alloys in the aged condition by quenching rather than air cooling from the heat-treating temperature, general practice is to air-cool magnesium alloys. All the work discussed in this paper is based, therefore, on aging studies performed on material air-cooled from the heat-treating temperature. This investigation was intended to be a study of commercially practical aging cycles; the tensile properties were determined, therefore, up to aging times of 25-hr duration.

The alloys used in this investigation were prepared in the laboratory by remelting commercial ingots of the appropriate composition according to the procedures described in a previous paper<sup>11</sup> as the "crucible method." All melts were given the standard superheating treatment in order to insure the maintenance of a uniform grain size of 0.003 to 0.004 in. Standard test bars, 6½ in. long with a 2½ in. long reduced section having a diameter of ½ in., were cast from these melts in green-sand molds using a four-bar pattern.

The alloys were heat treated according to the following schedules:

AZ92A alloy: 500° to 780°F in 2 hr + 780°F (24 hr)

AZ63A alloy: 500° to 740°F in 2 hr + 740°F (16 hr)

In commercial practice,<sup>12</sup> AZ92A alloy is heat treated at 770°F for 18 hr and AZ63A alloy is heat treated at 730°F for 10 hr. The slightly higher temperatures and longer periods of heat treatment were used in order to obtain as homogeneous a solid solution as possible and thus to minimize inconsistencies in the

data after aging. The preheat is the same as used commercially and is necessary for preventing liquation in segregated areas of nonequilibrium eutectic commonly found in cast Mg-Al-Zn alloys. All heat treatments were performed in circulating air furnaces electrically heated and controlled to  $\pm 5^\circ\text{F}$ . The atmosphere of the furnace was rendered protective by the maintenance of a concentration of 0.5 to 1.0 pct sulphur dioxide. Aging treatments were performed either in the same furnaces but without

Fig. 1—Tensile yield strength of AZ92A alloy. Temperature legend applies to Figs. 1 to 8.

Fig. 2—Tensile yield strength of AZ63A alloy.

\* ASTM designation for magnesium alloys:

AZ92A = Mg + 9Al + 2Zn + 0.2Mn

AZ63A = Mg + 6Al + 3Zn + 0.2Mn

T. E. LEONTIS and C. E. NELSON, Members AIME, are Associated with The Dow Chemical Co., Midland, Mich.

Discussion of this paper, TP 3015 E, may be sent (2 copies) to AIME by April 1, 1951. Manuscript, Oct. 9, 1950; revision Dec. 13, 1950. St. Louis Meeting, February 1951.

the use of sulphur dioxide, or in electrically heated oil baths controlled to  $\pm 1^\circ\text{F}$ .

The tensile properties were determined on the cast-to-size test bars without machining the surface. Most of the property values are the average of eight determinations, one bar being taken from each of eight separately cast batches of each alloy. Yield strength values are based on 0.2 pct offset; elongations are over a 2-in. gage length.

The dimensional changes accompanying aging were determined on the same type of cast bars. After solution heat treatment, the shoulders of the bars were machined to a diameter of 0.675 in. and the ends were faced parallel to a length of  $5.7 \pm 0.05$  in. and polished to a fineness of 1/0 grit emery paper. All measurements of length were made with a dial gage mounted on a specially constructed fixture. The smallest division on the gage was 0.0001 in. All measurements were made in a constant-temperature room after the bars had been allowed to stand in the room for at least 1 hr. The actual temperature at the time of measuring was recorded and all length readings were reduced to equivalent lengths at  $80^\circ\text{F}$ .

### Tensile Properties and Hardness

The tensile yield strength, elongation, and hardness of AZ92A and AZ63A alloys are presented as a function of aging time for a series of aging temperatures in Figs. 1 to 6, inclusive.

The tensile strengths have not been plotted in the same way because of the slight change that takes place in this property upon aging. Tensile strength

values for selected aging times at all aging temperatures are given in Table I. The tensile strength of AZ92A does not deviate significantly from the value of 40,000 psi in the solution heat-treated state. The same is true for AZ63A alloy except after extended aging times at the higher aging temperatures.

The aging curves in Figs. 1 to 6 show that these magnesium alloys exhibit a considerable degree of age hardening as measured by the increase in yield strength and hardness and the decrease in ductility with increasing aging time. The curves follow the general S-curve trends observed in all age-hardening alloy systems. Rate of increase in strength and hardness increases with increasing aging temperature and the maximum property decreases with increasing temperature.

The higher alloy content of AZ92A alloy produces a greater rate of aging in this alloy than that exhibited by AZ63A alloy. Also, significantly higher strength and somewhat lower ductility are developed in AZ92A alloy. Although aging of AZ63A alloy at  $300^\circ$  and  $350^\circ\text{F}$  has not been extended in this study to sufficiently long times to produce maximum strength at these temperatures, previous work in our laboratory has shown that yield strengths not significantly greater than those obtained at  $375^\circ$  and  $400^\circ\text{F}$  are produced by aging at the lower temperatures for as long as one month.

### Growth

The growth of the two alloys under consideration was determined over a wide range of aging temperatures. The results are depicted in the form of growth vs. time curves in Figs. 7 and 8; the data on these graphs were obtained on material originally in the solution heat-treated condition. All the curves have the shape characteristics of reactions following a process of nucleation and growth.

As in the case of the property changes accompanying aging, AZ92A alloy exhibits a greater amount and faster rate of growth than AZ63A alloy. Neither

Fig. 3—Elongation of AZ92A alloy.

Fig. 4—Elongation of AZ63A alloy.

Fig. 5—Brinell hardness of AZ92A alloy.

Fig. 6 (left) — Brinell hardness of AZ63A alloy.

Fig. 7 (above) — Growth of AZ63A and AZ92A alloys.

AZ92A nor AZ63A attains maximum growth at 212°F in 10,000 hr of aging. A few growth measurements have been performed on material in the as-cast condition. The results of these tests, tabulated in Table II, indicate a substantial amount of aluminum and zinc are retained in solid solution when these alloys cool from the freezing temperature. Unfortunately, these measurements have not been carried to sufficiently long aging times to arrive at equilibrium values. Nevertheless, they do indicate that growth is encountered in as-cast material. Fig. 9 shows the variation in the amount of growth with temperature. The marked decrease in growth of both alloys at temperatures above 425°F is closely associated with the rapid increase in solubility of aluminum and zinc in magnesium at these temperatures. These curves also show that the present commercial aging treatment of 5 hr at 425°F is a good selection. This aging cycle contributes nearly maximum strength properties (Figs. 1 and 2) as well as high dimensional stability in as short an aging time as can be obtained. Furthermore, there is considerable advantage in practice in having one aging treatment for both alloys.

Another important consideration in castings is the relief of residual stresses that may be present in the as-cast state or that may arise from cooling after

heat treatment. It has been determined by Found and Pittsley<sup>13</sup> that the magnitude of residual stresses in magnesium-alloy castings is considerably lower than that generally encountered in other alloys. The work of these investigators also shows that stresses arising in AZ63A and AZ92A alloys in cooling from the heat-treating temperature are essentially eliminated by the aging treatment recommended in the present paper.

The time required to attain a certain percentage of the maximum possible growth at each temperature is a measure of the rate of precipitation at that temperature. A linear relation should exist between the logarithm of this time quantity and the reciprocal of the absolute temperature. Such a plot is shown in Fig. 10. Deviations from the linear relationship are exhibited by both alloys at the higher temperatures. The marked increase in the solid solubility of the alloying elements in magnesium at temperatures greater than 450°F decreases the driving force of the precipitation reaction at these temperatures. The effect is naturally more pronounced in the alloy of lower total alloy content.

### Microstructure

In Figs. 11 and 12 are shown selected microstructures of AZ92A and AZ63A alloys after various degrees of aging. The structures of the alloys in the

Fig. 9 (right)—Growth vs. temperature.

solution heat-treated condition is not shown inasmuch as they have appeared in the previous publications.<sup>10, 14</sup> This solution treatment dissolves the  $Mg_{17}Al_{12}$  compound in the magnesium phase but leaves small particles of Mn and  $Mg_2Si$  undissolved. Solution heat treatment produces an increase in tensile strength and ductility as shown in Table III.

The structures shown in the accompanying figures illustrate that there are two distinct types of precipitate in the aged condition of Mg-Al-Zn alloys. One is the discontinuous type which forms at the grain boundaries and resembles pearlite in appearance. The other is the continuous type which appears within the grains and forms a Widmanstätten pattern.

In the temperature range investigated, the first precipitate to form is the pearlitic type along the grain boundaries. As aging proceeds, a finely divided precipitate appears within the grains, usually beginning at the center of each grain and proceeding outward to the grain-boundary precipitate. The discontinuous precipitate consists of alternate plates of  $Mg_{17}Al_{12}$  and Mg solid solution. The higher the temperature, the greater is the lamellar spacing of the pearlitic precipitate. At a magnification of 250X, the lamellae are not resolved in either alloy aged at temperatures below 425°F. In the micrographs presented here, the true nature of this pearlitic precipitate can be seen only in AZ63A alloy aged at 500°F (Fig. 12f). In structures produced in AZ92A alloy by aging at temperatures above 425°F, it is difficult to distinguish the two types of precipitate (Fig. 11f).

The more rapid rate of aging of AZ92A alloy is again demonstrated by the micrographs. As an example, comparison of Figs. 11b with 12a shows that after the same aging treatment, AZ92A alloy has

considerably more precipitate than AZ63A. Similar comparisons can be made for other aging treatments.

### Summary

The aging studies on two commercial Mg-Al-Zn alloys, AZ63A and AZ92A, reported in this paper show that a wide variation in the properties can be attained by selection of aging temperature and time. Properties typical of these two alloys in the fully aged condition are given in Table IV.

Although both AZ63A and AZ92A alloys exhibit a measurable amount of growth when aged after solution heat treatment, suitable aging treatments render these alloys dimensionally stable to subsequent exposure at temperatures prevailing in engine applications. The figures in Table V indicate the maximum possible growth that can be expected in AZ63A and AZ92A alloys in the heat-treated and in

Table IV. Typical Properties of Fully Aged AZ92A and AZ63A

|       | E, Pct | 1000 Psi |    | BHN |
|-------|--------|----------|----|-----|

# Mechanical Properties of Stainless Steel Powder

by

Arthur H. Grobe

and

George A. Roberts

**Tensile, hardness and density properties are presented for a new 18-8 stainless steel powder for the —50, —100, and —140 mesh cuts and also for a prepared blend containing 62 pct —325 mesh powder. The data were obtained for sintering temperatures of 2100° to 2350°F and for compacting pressures of 30 to 50 tons per sq in.**

A NEED has existed for a stainless steel powder of uniform composition from particle to particle, which could be readily molded and sintered, and which would yield moderate to high strength and ductility when processed into parts by standard powder metallurgy techniques. The literature reveals that previously available powders have been lacking in one or several of these desirable characteristics. Originally attempts to produce stainless steel powder by blending and diffusing elemental metal powders were unsuccessful.<sup>1</sup> A truly alloyed stainless steel powder reported by Dale in 1947 yielded reasonable mechanical properties but required an exceptionally high sintering temperature of 2400°F in pure dry hydrogen.<sup>1</sup> A later development reported in 1950 by Stern provided a stainless type powder of excellent molding properties<sup>2</sup> but this powder likewise required sintering at temperatures over 2350°F and did not yield properties as high as those previously reported. The powder was not truly alloyed prior to sintering.

A prealloyed stainless steel powder has been developed that is readily moldable at 30 to 50 tons per sq in., can be sintered at low temperatures

(2100° to 2300°F), and which yields compacts with both high strength and ductility. The powder is prepared by the liquid disintegration method,<sup>3</sup> direct from molten metal. Early attempts to make 18 pct Cr, 8 pct Ni stainless steel powder by this method did not produce a usable powder for pressing and sintering because of a preponderance of spherical particles with relatively high, surface oxide content. It was learned that silicon additions to iron alloys, powdered by this process, gave bright powder of low-oxide content and such additions were made to 18-8 stainless with similar results. An attendant change in particle shape occurred reducing the number of spheroids materially. The optimum composition which has been studied and is reported here contains approximately 2.5 pct Si. Silicon additions to stainless steel of the 18-8 type improve the resistance to high-temperature oxidation and promote the formation of ferrite. Corrosion resistance is, however, controlled by chromium content and even though ferrite may exist the corrosion resistance is not generally impaired.<sup>4</sup>

## Experimental Procedure

A detailed study of the 18-8, 2.5 pct Si powder has been made in accordance with the following outline:

1. Four blends
  - a. — 50 mesh
  - b. —100 mesh

ARTHUR H. GROBE and GEORGE A. ROBERTS are associated with the Metallurgical Dept., Vanadium-Alloys Steel Co., Latrobe, Pa.

Discussion of this paper, TP 3007 E, may be sent (2 copies) to AIME by April 1, 1951. Manuscript, Oct. 17, 1950. St. Louis Meeting, February 1951.

- c. —140 mesh
- d. —100 mesh special mixture with 62 pct —325 mesh

## 2. Properties of powder blends

- a. Apparent density
- b. Flow rate
- c. Compression ratio

## 3. Pressing and sintering

Density, shrinkage and mechanical properties

### a. All blends sintered (sintering time 45 min)

- 1) Pressures—30, 40, 50 tons per sq in.
- 2) Temperatures—2100°, 2200°, 2300°F

### b. All blends sintered—coined\*—resintered (both sintering times 45 min)

- 1) Pressures—30, 40, 50 tons per sq in.
- 2) Temperatures—2100°, 2200°, 2300°F

### c. —100 mesh blend sintered (sintering temperature 2250°F)

- 1) Pressure—30, 40, 50 tons per sq in.
- 2) Times of sintering—15, 45, 90, 180, 300 min

### d. —100 mesh blend sintered—coined (sintering temperatures 2250°F)

- 1) Pressures—30, 40, 50 tons per sq in.
- 2) Times of sintering—15, 45, 90, 180, 300 min

### e. —100 mesh blend sintered—coined—resintered (sintering temperature 2250°F)

- 1) Pressures—30, 40, 50 tons per sq in.
- 2) Times of sintering—15, 45, 90, 130, 300 min

## 4. Properties of wrought material of same composition

Apparent density was determined using the Hall flowmeter with the 25 cc cup. Flow rate was determined in accordance with Metal Powder Association Standard 3-45T. Compression ratio is calculated as the ratio of the green to the apparent density.

Density of pressed and sintered compacts was measured on specimens ½ in. in diam and weighing 12 g. Tensile bars were made in a split die producing

\* All coining pressures the same as original pressing pressure.

a square-ended specimen 4 in. x ¼ in. thick. The width at each end was ⅜ in. with a reduced center section ¼ in. wide to provide a gage length of 1 in. All compacts were pressed in a die lubricated with calcium stearate dissolved in carbon tetrachloride. Coining was performed in the same dies, and accordingly some difficulty was encountered in completely coining samples which had exhibited large amounts of shrinkage during the initial sintering.

Sintering was conducted in a tube furnace with a hydrogen atmosphere. Tank hydrogen was deoxidized with platinized alumina and dried in an Electro-dryer. Samples reached the sintering temperature in 15 to 20 min and all sintering times reported are times at temperature. Cooling was accomplished in the same atmosphere in the water-cooled end of the tube, where the samples were held for 30 min.

All samples were measured and weighed before and after each treatment. Shrinkage is recorded as the change in length of the 4-in. tensile specimens. Rockwell F hardness, tensile strength, and elongation values were determined for all treatments on the tensile samples.

A 30-lb induction heat was produced of the same

Table II. Properties of the —50 Mesh Powder

\* Sintering time was 45 min at temperature.

† Shrinkage was measured on the 4 in. length of the tensile specimen.

‡ Specimen broke beyond gage marks.

\* Sintering time was 45 min at temperature.

† Shrinkage was measured on the 4 in. length of the tensile specimen.

‡ Specimen broke beyond gage marks.

composition and forged from a 3-in. ingot to a  $\frac{7}{8}$  in. sq bar. Tensile specimens were machined of the same size and design as those employed for the powder compacts.

### Experimental Results

The powder employed was of the following composition: C, 0.09 pct; Si, 2.42; Mn, 0.63; S, 0.007; P, 0.019; Cr, 17.48; and Ni, 8.02.

All of the blends tested molded very well. For commercial applications the —50 mesh powder would yield best moldability at 40 to 50 tons. Standard —100 mesh powder is equivalent to this at 40 tons, while the finer powders have commercially satisfactory green strength at 30 tons.

The basic powder properties and the sieve analyses

of the four blends are shown in Table I. This is fundamentally a free flowing powder in all blends with an apparent density of approximately 2.9 g per cc.

Tables II to V, inclusive, present the complete property information for the four blends or cuts studied when pressed at 30 to 50 tons per sq in. and sintered for 45 min at 2100° to 2300°F. In the first column the figures "30-0", for example, indicate pressing-sintering-coining and resintering.

There is a general tendency for the tensile strength and elongation to increase slightly as the particle size decreases. This is especially pronounced at low densities. On the other hand, shrinkage increases greatly as the average particle size becomes finer.

Table IV. Properties of —140 Mesh Powder

| Compacting and Coining Pressure, Tons per sq in. | Sintering* Temp., °F | Tensile Strength, Psi | Elongation, Pct in 1 in. | Hardness, Rockwell F | Green Density, g per cc | Density After First Sinter, g per cc | Coining Density, g per cc | Density After Final Sinter, g per cc | Shrinkage† During First Sinter, Pct | Shrinkage† During Second Sinter, Pct |

\* Sintering time was 45 min at temperature.

† Shrinkage was measured on the 4 in. length of the tensile specimen.

‡ Specimen broke beyond gage marks.

Fig. 1—Tensile strength vs. sintering temperature for —100 mesh powder.  
Sintered, coined, and resintered. Each sintering 45 min at temperature. Pressed and coined at pressures shown.

For commercial applications a shrinkage of 1 to 1.4 pct is practical, and accordingly —50 mesh powder could be sintered at 2300°F for 45 min while the very finest powder tested should be sintered at 2200°F if shrinkage is the prime consideration.

The detailed study made of the —100 mesh powder sintered at 2250°F was predicated on the shrinkage consideration which indicated this temperature as optimum for the powder. Data shown in Table VI record all properties obtained by varying the sintering time from 15 to 300 min and the pressing and coining pressures from 30 to 50 tons per sq in. In this instance tensile tests were made on bars sintered and coined with no subsequent resintering in addition to the usual conditions in which sintering was the final operation. It is to be particularly noted that while the tensile strength is increased by coining, the elongation is reduced markedly. Nevertheless, elongations still remain at a relatively high level for powder parts. One factor not recorded in these data is the great increase in yield strength that is a

natural result of the coining operation and is of engineering importance.

Selected information from the tables has been assembled into graph form in Fig. 1 to show the trends of properties as a function of the major commercial variables for the standard —100 mesh powder.

The tensile strength of —100 mesh powder increases approximately 100 pct as the sintering temperature is increased from 2100° to 2300°F. A consistent but smaller improvement results from increasing the pressure from 30 to 50 tons per sq in. These results apply to single pressing and sintering. Fig. 1 refers to these same variables but after coining and resintering. The properties after the treatment at 2100°F are equal to those of single sintering at 2300°F. Values of tensile strength over 80,000 psi are obtained at 2300°F with a pressing and coining pressure of 50 tons per sq in.

The increase in strength by lengthening the sintering time beyond 1 hr is slight, but the increase from 15 to 45 min is significant. The increased tensile strength as a result of coining without resintering is apparent.

The tabular shrinkage data are not as consistent as would be obtained commercially, since each specimen in this entire series of tests was individually pressed and sintered, thus increasing the difficulty of obtaining precise control.

From the tabular data it is apparent that the tensile strength and elongation increase simultaneously and in a regular manner except for those samples on which the final operation was coining. In Fig. 2 the validity of this relationship is established. Open circles are plotted for each and every tensile specimen broken, regardless of screen size, pressing, or sintering conditions. The curve is a straight line until tensile strengths of 85,000 psi are reached, when the elongation increases at a more rapid rate. This is caused by the close approach of the tensile strength to that of the wrought material, whereas the elongation is still considerably lower than that of the wrought material. Coined samples show a lower elongation and a poorer correlation than sintered samples (see solid circles in Fig. 2).

\* Sintering time was 45 min at temperature.

† Shrinkage was measured on the 4 in. length of the tensile specimen.

‡ Specimen broke beyond gage marks.

Microstructural examination of these sintered stainless steel compacts reveals that at 2200°F and higher sintering temperatures ferrite is forming at grain boundaries. The amount of ferrite increases as the sintering temperature is raised as is shown in Figs. 3 and 4. This ferrite is the result of the high silicon content of the powder and the reduced carbon after sintering (the latter results from the decarburizing action of the hydrogen gas and of the small amount of oxide present). A small amount of ferrite is present for the short sintering treatment at 2200°F, Fig. 3, and with longer sintering times at higher temperatures this phase becomes almost continuous, Fig. 4. A few samples sintered at 2350°F show approximately 15 to 20 pct of ferrite as a continuous phase.

Because of the high strengths obtained on these powder compacts of stainless steel and the lack of data on a wrought material of similar analysis, a lot of stainless steel of the following composition was produced from a small ingot: C, 0.09 pct; Si, 2.65; Mn, 0.71; S, 0.006; P, 0.022; Cr, 17.74; and Ni, 8.32; density, 7.73 g per cc.

The tensile properties obtained are charted in Table VII. It is apparent that the high values of tensile strength obtained for these stainless steel

Fig. 2—Correlation of elongation and tensile strength for tensile specimens of all powders for all conditions. Solid circles, —100 mesh powder sintered at 2250°F in the as-coined condition.

Table VI. Properties of —100 Mesh Powder at 2250°F

powder compacts by normal powder metallurgy techniques approach those of the wrought material. Ductility is, as expected, relatively lower and could only be increased by increasing the density through extra cold coining and sintering or hot coining operations.

The tensile samples of wrought material had visible amounts of ferrite only at the surfaces which were decarburized during the hydrogen treatment. This is probably responsible for the slight drop in tensile strength as the treating temperature was raised and confirms the supposition that the ferrite in the compacts from the stainless steel powder is partly the result of decarburization throughout the slightly porous compact.

The carbon content of the compacts decreased to at least 0.05 pct at 2100°F and to 0.00 to 0.02 pct at 2300°F. This loss of carbon is accompanied by a weight loss due to the reduction of oxides which under even the most severe conditions of sintering times and temperatures did not exceed 0.35 pct.

### Conclusions

1. A prealloyed 18-8 stainless steel powder has been developed that is readily moldable, can be sintered at temperatures as low as 2100°F in a hydrogen atmosphere, and yields compacts with higher strengths and ductility than heretofore possible by standard powder metallurgy techniques.

2. The powder containing 2.50 pct Si is free flowing with an apparent density of 2.9 g per cc and a maximum weight loss in hydrogen of 0.35 pct.

3. Optimum pressing and sintering conditions vary with the screen analysis, the finer powders being capable of handling at slightly lower pressures and temperatures. For —100 mesh standard powder pressing at 40 tons per sq in. and sintering for 45 min at 2250°F gives a tensile strength of 40,000 psi and an elongation of 15 pct. Coining at 40 tons and resintering at 2250°F for 45 min provides a tensile strength of 65,000 psi and an elongation of 22 pct.

4. The highest properties realized for the —100 mesh powder were 87,000 psi tensile strength with 32 pct elongation. For a special blend of fine powder these values were 92,000 psi and 38 pct, respectively. These strength properties approach those for wrought material of the same composition.

5. Tensile strength and elongation show a straight-line relationship for this powder, regardless of screen analysis or pressing and sintering conditions. Coining, not followed by resintering, however, lowers elongation while raising tensile strength.

6. Silicon promotes the formation of small quantities of ferrite at high sintering temperatures, especially as the hydrogen atmosphere reduces the carbon content of the compacts to below 0.02 pct.

# Preparation of Titanium Tetrachloride from Rutile

by C. H. Gorski

A method for preparing titanium tetrachloride is described which consists of reducing rutile with coke and chlorinating the reduced product at 200° to 500°C. The crude distillate is purified by treatment with copper powder and distillation. Recoveries, exceeding 90 pct of the titanium in the rutile, were obtained.

IN recent years considerable interest in metallic titanium has been aroused because of its outstanding physical and chemical properties. The present commercial processes for preparing titanium are modifications of the Kroll<sup>1</sup> process and consist essentially of the reduction of titanium tetrachloride with magnesium in an inert atmosphere to produce metallic titanium with magnesium chloride as a byproduct.

At present,<sup>2</sup> commercial titanium tetrachloride costs \$0.32 a pound, which makes the price of the included titanium \$1.28 a pound. As the titanium tetrachloride must be purified further before processing into metal, its ultimate cost obviously will be higher. Consequently, one of the prime requisites for the production of lower cost titanium metal is a source of low-cost titanium tetrachloride.

Recently, Knickerbocker, Gorski, Kenworthy, and Starliper<sup>3</sup> described a method for preparing titanium tetrachloride from low-grade Arkansas rutile by smelting the rutile with pyrite and coke to form a titanium matte and then chlorinating the titanium matte to prepare a crude titanium tetrachloride. This process had several inherent advantages. Low-grade rutile concentrates were utilized, the chlorination temperature was relatively low (approximately 200°C), and the reaction was strongly exothermic. However, this process had several disadvantages, chief of them being the rather low recoveries of titanium tetrachloride (65 to 81 pct) and the difficulty in purifying the crude titanium tetrachloride obtained.

Because of the high-titanium and low-iron con-

tents of rutile as compared to ilmenite, rutile should be of greater potential value as a source of titanium tetrachloride than ilmenite. Rutile, however, is not chlorinated directly in commercial practice, because reaction temperatures above 700°C are required, at which point chlorine attacks most of the common materials of construction. The process now in use consists of converting the titanium in rutile to the cyanonitride by high-temperature reduction in an electric furnace, and then chlorinating this compound. The disadvantages of this process are the difficulty of producing the cyanonitride, the use of high-grade rutile concentrates in the charge, and the presence of several percent of silicon tetrachloride in the finished product. It would be of considerable interest to develop a new process for the preparation of titanium tetrachloride from rutile by chlorination at 200° to 500°C.

## Process Development

Several investigators<sup>4-7</sup> have studied the reduction of titanium dioxide with carbon in an effort to prepare titanium monoxide. Invariably, the titanium monoxide formed in this manner was not pure, as it contained titanium carbide and one or more of the lower oxides of titanium. As these lower oxides of titanium are more reactive chemically than rutile, and as it is known that titanium carbide may be chlorinated readily, a study was made of the chlorination of carbon-reduced rutile. A sample of rutile concentrates from Hot Spring County, Ark., containing 76.19 pct TiO<sub>2</sub>, 5.65 pct Fe<sub>2</sub>O<sub>3</sub>, 4.18 pct SiO<sub>2</sub>, and 2.88 pct Al<sub>2</sub>O<sub>3</sub>, was used for this investigation.

The experimental procedure consisted of making an intimate mixture of —100-mesh rutile and petroleum coke, adding water and molasses as a binder to form a paste, charging into a graphite crucible that was covered, except for a vent to allow the

escape of gases, and heating with a 3.0 kva high-frequency induction furnace. The charge was held at the reaction temperature (1050° to 1400°C) for 30 min and permitted to cool in the absence of air. After cooling, the charge, which was in the form of a sinter, was ground to —100-mesh, mixed with 30 pct of its weight of —100-mesh petroleum coke, and chlorinated. (The petroleum coke had the following chemical analysis: 79.0 pct fixed carbon, 13.8 pct volatile combustible matter, 6.5 pct ash, and 0.72 pct moisture.) Chlorination was effected in a quartz tube heated by a tube furnace held in a vertical position. The chlorine flowed up through the charge, and the reaction product, which consisted essentially of titanium tetrachloride with minor amounts of ferric chloride, was passed through the top end of the quartz tube, condensed in an air condenser, and collected in a 500-ml wide-mouthed Erlenmeyer flask. The exit gas was bubbled through a flask containing concentrated hydrochloric acid to keep air from entering the system in case the chlorine flow was halted temporarily. The crude titanium tetrachloride was purified by one of several methods described later.

#### Effect of Experimental Variables

Several series of runs were made to study the effect of varying the amount of petroleum coke and reaction temperature on the reduction of rutile and subsequent chlorination of the reduced product.

In the first series of experiments, each charge consisted of 250 g of rutile concentrates, 37 g of petroleum coke, 14 g of molasses, and 33 g of water. Sufficient coke was used so that its fixed carbon content was approximately equal to the stoichiometric amount of carbon necessary to reduce the titanium dioxide content of the rutile concentrates to titanium monoxide. The samples were heated for 30 min at 1100° to 1400°C. The chemical analyses of these reduced products are shown in Table I. The amounts of titanium and combined carbon in the samples decreased as the reduction temperature was lowered.

Chlorination of the reaction products at 500°C showed titanium recoveries of 98 pct or more could be obtained from the samples furnace at 1300° and 1400°C. The samples furnace at 1100° to 1200°C gave titanium recoveries of approximately 90 pct.

In another series of experiments the temperature was held constant at 1400°C, the amount of rutile was 250 g, the amount of petroleum coke used was increased from 37 g in stages to 66.6 g, and the

molasses was similarly increased from 14.0 to 15.8 g. Chlorination of these samples at 500°C gave titanium recoveries of 95 to 99 pct. Increasing the amount of coke in the induction furnace charges had no marked effect upon the recovery of titanium by chlorination at 500°C. When the amount of coke was increased, however, it was possible to lower the chlorination temperature to as low as 200°C and recover more than 90 pct of the titanium.

An overall summary of several runs, showing the chemical analyses of the chlorination residues, the chlorination conditions, the conditions under which the rutile was reduced, and the titanium recoveries obtained, is shown in Table II. In these runs each sample was chlorinated until there was no further reaction, as indicated by the absence of vapor passing through the condenser.

More than 95 pct titanium could be recovered consistently when rutile was reduced at 1200° to 1400°C with an excess of petroleum coke and then chlorinated at 500°C. When the reduction temperature was less than 1050°C, the titanium recovery was lowered considerably.

Further experimental work showed that the reduced rutile could be chlorinated at temperatures as low as 136° to 144°C, approximately the normal boiling point of titanium tetrachloride, with a recovery of 84.6 pct of the titanium in the rutile.

#### Purification of Titanium Tetrachloride

The product obtained by the chlorination of reduced rutile consisted primarily of titanium tetrachloride and ferric chloride with minor amounts of sulphur chloride and other unidentified compounds. Simple distillation of this crude product gave a titanium tetrachloride containing 0.27 pct iron and 0.09 pct sulphur. This product obviously is not pure enough for use in preparing titanium metal.

Several schemes of purification were tried in an

effort to prepare titanium tetrachloride at least as pure as titanium tetrachloride currently sold as a reagent of cp grade. These consisted of treatment of single-distilled titanium tetrachloride with hydrogen sulphide followed by distillation, treatment of single-distilled titanium tetrachloride with calcium hydride<sup>8</sup> followed by distillation, direct treatment of crude titanium tetrachloride with copper powder followed by distillation, and treatment of single-distilled titanium tetrachloride with copper powder followed by distillation.

The most effective method of purification consisted of agitating the single-distilled titanium tetrachloride with 2 pct of its weight of copper powder for 1 hr at 100°C and again distilling. A water-white distillate was obtained that was spectrographically equal to or better than cp titanium tetrachloride in every respect. The titanium recovery in this step should be 95 pct or better.

Hydrogen sulphide gave promising results as a purification agent. Further research probably would show it to be as effective as the copper-powder treatment. Calcium hydride was ineffective as a purification agent. The titanium tetrachloride prepared by the hydride addition was considerably higher in vanadium than cp titanium tetrachloride.

The method of analyzing titanium tetrachloride has been outlined by Stoddard and Pietz<sup>9</sup> and consisted of hydrolyzing the titanium tetrachloride and running a spectrographic analysis of the product of hydrolysis. A sample of titanium tetrachloride, currently sold as a reagent of cp grade, was run in the same manner and was compared with each of the titanium tetrachloride samples prepared in the laboratory.

A chemical analysis of cp titanium tetrachloride showed 0.006 pct iron and 0.008 pct silicon. The pure titanium tetrachloride made by treatment with copper followed by distillation was water-white and by spectrographic analysis contained equal or smaller amounts of impurities than the commercial cp product. The cp titanium tetrachloride was straw-colored. This discoloration was caused partly by the presence of vanadium compounds and partly by chlorine dissolved in the liquid.

### X-Ray Analysis

Several X-ray diffraction patterns were made of some of the samples of reduced rutile in an effort to identify the major constituents. The data were

obtained with a 143.2 mm diam Debye-Sherrer camera. The sample was mounted on a fine-drawn pyrex fiber with collodion and rotated in an X-ray beam passing through a 0.030-in. diam collimator for a 3-hr exposure.

The X-ray diffraction patterns for titanium carbide and titanium monoxide are very similar, and it was impossible to differentiate between these compounds by X-ray analysis. The samples reduced at 1300° to 1400°C were essentially mixtures of titanium carbide and titanium monoxide, whereas those reduced at 1100° to 1200°C contained minor amounts of titanium suboxide ( $Ti_2O_3$ ) in addition to titanium carbide and monoxide. Diffraction patterns of rutile and of titanium carbide are shown in Figs. 1 to 3.

### Summary

A relatively simple method of preparing titanium tetrachloride has been developed. This process consists in reducing the rutile with coke at 1100° to 1400°C to form a reduction product identified as a mixture of titanium suboxides and minor amounts of titanium carbide. This reduced product is then chlorinated at 200° to 500°C to form a crude titanium tetrachloride, which may be purified by distillation and treating the singly distilled product with copper powder and redistilling. The product thus obtained was equal to or greater in purity than titanium tetrachloride currently sold as a reagent of cp purity. In this manner 90 pct or more of the titanium in the rutile has been recovered.

The chief advantage of this method of preparing titanium tetrachloride is the low chlorination temperatures (200° to 500°C). The product is substantially free from silicon compounds, thus making the purification simpler than the purification of commercial, technical grade titanium tetrachloride, which usually contains several percent of silicon tetrachloride.

### Acknowledgments

Acknowledgment is made to the many associates in the Metallurgical Branch who assisted in this work, particularly to J. P. Dowdy, who made many of the chemical determinations, and Fred Hoertel for the X-ray diffraction patterns of many of the samples of reduced rutile.

\* Excess of coke means the excess above that necessary to reduce the titanium dioxide content of the rutile to titanium monoxide. In these calculations it was assumed that only the fixed carbon content of the coke took part in the reaction.

# Reverse Leaching of Zinc Calcine

by L. P. Davidson, R. K. Carpenter, and H. J. Tschirner

THE electrolytic zinc plant of the American Zinc Co. of Illinois, at Monsanto, was expanded in 1943 to a capacity of 100 tons of slab zinc daily. This capacity was not attained because of inability of the leaching plant to deliver an adequate amount of solution for electrolysis. Changing the leaching method so that the acid was added to the roasted zinc material reversed the usual procedure and made it possible to attain the desired capacity. The conditions which prevented satisfactory work before this change and the difficulties which arose in reversing the usual leaching procedure are described.

The "reverse" leach operation as now practiced is carried out as follows: All the calcine to be leached is fed continuously to a slurry mixing tank. About one third of the acid to be used is fed to the tank with the calcine. The slurry is discharged continuously to a Dorr duplex classifier in closed circuit with a Hardinge mill. The classifier overflow is pumped to any of six leaching tanks where the leach is completed.

A finished leach is discharged through Allen-Sherman-Hoff pumps to Dorr thickeners, from which the overflow goes to the zinc dust purification and the underflow to vacuum filters.

This change in leaching procedure from the usual one of adding calcine to a large amount of acid made it possible to provide an adequate amount of purified solution to the electrolyzing division and at the same time filter and dry all the residue produced. Operating savings in reagents and better metallurgical recoveries were also important benefits.

The original flowsheet of the leaching plant provided leaching, sedimentation of the insoluble residue, and purification of the neutral zinc sulphate solution with zinc dust. The thickened residue was filtered and washed. The purification cake of excess zinc dust, precipitated copper and cadmium, and any insoluble residue was filtered off on plate-and-frame duplex classifier.

Settlement in the thickeners was inadequate and the suspended solids in the thickener overflow gave rise to filtration difficulties after the zinc dust purification. Further, the filtration and washing of the leach residue was poor, and it became necessary to pump a large amount of unwashed or poorly washed residue to storage ponds outside the plant building.

Two causes of the poor settling and filtration were determined: Soluble silica and ferrous iron in the calcine treated. The latter was a result of poor roasting and with more experience ceased to be a major

problem. The silica was a normal constituent of the feed and the working out of the problem became a matter of controlling its solubility.

The obvious method to render the silica insoluble was by intensive roasting. This, however, met with total failure as such roasting resulted in silicates, probably zinc, soluble in the 13 pct acid used for leaching. Attempts were made to coagulate the fine gelatinous slime with addition agents. Glue, lime, starch, beef-blood serum and others were tried without success. All the suggested tried-and-tested means of operating the thickeners gave no consistently good results. Variations in leaching time, in addition of calcine to the leaching tanks, "conditioning" of the pulp by prolonged agitation, immediate discharge of the leach upon completion to avoid breaking up flocs were all tried and given up as ineffective.

Byron Marquis, of Singmaster and Breyer, worked with the plant staff on a beaker scale until a leaching procedure was developed which gave consistent results and a promise of overcoming the difficulties which had plagued the plant operation. It was suggested that the difference in solubility of silicates and zinc oxide in sulphuric acid could be made use of in a leaching method where the acidity was controlled carefully. Such control is possible when acid is added to a slurry of calcine. This process reverses the normal procedure of adding calcine to a vessel of acid, hence the term "reverse leach" was applied.

In this way, the overall acid concentration can be kept very low. In the tests made, it did not exceed 0.05 g per liter free sulphuric acid.

Numerous advantages were realized when no silicates were taken into solution and later precipitated as a bulky gel. The gel had made reasonable thickening and filtration of the leach pulp and practical drying of the residue impossible. When the gel was eliminated, thickening rates were increased as much as five times. The volume of residue after thickening represented about 10 pct of the total leach pulp and had been as high as 95 pct when the gel was present. The thickened pulp was filterable and the filtered cake was dried readily after washing.

The zinc extraction from the calcine was slightly lower. This was more than compensated for by the increase in zinc recovered in solution from zinc which had been trapped in the gelatinous residue. The amount of copper recovered was lower. However, the amounts of other impurities, such as arsenic, antimony, and germanium, taken into solution were lower. This was particularly true of antimony. Since the inception of reverse leaching, no concentrates have failed to yield solutions free of antimony even when present in the calcine to the extent of 0.2 to 0.3 pct.

Oxidation of ferrous iron is a problem of reverse leaching. Ferrous hydrate does not precipitate at pH 5.3 to 5.4 where a leach is finished. The usual oxida-

L. P. DAVIDSON, Member AIME, is General Superintendent, R. K. CARPENTER is Research Engineer, and H. J. TSCHIRNER, Junior Member AIME, is Superintendent of Electrolyzing and Casting, American Zinc Co. of Illinois, Monsanto, Ill.

Discussion of this paper, TP 3001 D, may be sent (2 copies) to AIME by April 1, 1951. Manuscript, Sept. 1, 1950; revised, Nov. 28, 1950. St. Louis Meeting, February 1951.

tion to the ferric state with manganese dioxide is not possible because of the low concentration or absence of free sulphuric acid. An excess of calcine will precipitate the ferrous iron but this method wastes calcine, results in a very viscous pulp which tends to cake in pumps and pipe lines, and places an undue load on the thickener mechanisms. Soluble copper will catalyze the oxidation of ferrous iron to the ferric state when air is passed through the pulp. A low-pressure air line was introduced into each leaching tank and the soluble copper normally present in the solution was sufficient for oxidation.

The question arose as to the solution of zinc oxide in sulphuric acid at concentrations of 0.05 g per liter. Tests showed that when stoichiometric quantities of zinc oxide and 200 g per liter sulphuric acid were reverse leached, 98 pct of the zinc oxide was dissolved. After 15 min the pH was 2.5. An additional 2 pct zinc oxide raised the pH to 5.8, the maximum which could be attained, even with 100 pct excess.

After the leaching technique had been developed, complete cyclic electrolyzing tests were made with solutions from various calcines. When these results proved satisfactory, pilot-plant work was started to determine equipment for this process on plant scale.

A slurry of zinc oxide and zinc sulphate solution will cement and "set up." This slurry could not be made in the leaching tanks because of this tendency and because zinc extraction from the large cemented lumps is low. The preparation of the slurry, of necessity, had to be carried out in equipment outside the leach tanks. Standard classifying, grinding and pumping equipment was found to be adequate. Many trials were made before a satisfactory mixing vessel was developed.

### Development of Equipment

The reverse leach flowsheet, as illustrated in Fig. 1, was installed in the plant in the summer of 1944. A Merrick Feed-O-Weight was chosen to weigh and feed the calcine to the mixing equipment. With this, the collection and feeding of the calcine from the 12 storage bins became automatic. A 6-in. horizontal screw feeder was provided in the pyramidal bottom of each bin. The screw is totally encased except that portion in the bin which operates in a semicircular trough. Each is motor driven through a Reeves variable speed control. Two 10-in. collection screws, each conveying the calcine from six bin feeders, discharge into the scale hopper of the Feed-O-Weight. Operation of the conveyors is intermittent and controlled by Bindicators on the scale hopper. This system permits the selection and blending of calcines to make up a uniform plant feed since the rate of withdrawal from any bin can be controlled.

The blended calcine was fed into the slurry mixer along with purified solution assaying 135 g per liter zinc. It was imperative to agitate this pulp continuously and guard against temperatures over 45°C, because such a slurry on standing or heating quickly formed a zinc oxy-sulphate cement.

The slurry mixer was a three volume-ton, top discharge tank provided with a 22 in. duplex turbo mixer driven by a 5 hp motor geared to 350 rpm. The impeller was 6 in. from the tank bottom. The overflowing slurry was laundered to a standard Dorr duplex classifier.

The oversize material from the classifier was ground in a 4½ ft x 16 in. conical Hardinge ball mill in closed circuit with the classifier. Classifier overflow was piped to a 125 gpm Allen-Sherman-Hoff

Fig. 1—Reverse leach flowsheet.

Packless rubber-lined pump and pumped through a 4-in. line to a 25 volume-ton Dorr slurry mixer used as a surge tank. A 4-in. circulating line was provided between the surge and leaching tanks.

The slurry was leached in 40 volume-ton, cone bottom, mechanically agitated tanks. These tanks, 14 ft deep x 10 ft in diam, are constructed of lead-lined steel with a 4-in. acid-proof brick inner-lining. A 1-in. copper line introduces compressed air beneath the center of the agitator shaft. These tanks discharge into a 5-in. copper manifold leading to two 500 gpm Allen-Sherman-Hoff Packless pumps, discharging in turn into three 50-ft Dorr thickeners in parallel.

The thickener overflow was laundered to the zinc dust purification tanks. The underflow was filtered and washed on Moore filters. The residue then was repulped with water and refiltered on three Eimco filters. The dewatered cake was dried in a rotary drier and shipped.

Within 24 hr of operation, all the slurry piping, except vertical sections, cemented shut. The cementing occurred first in valves, tees, and short nipples and progressed from there. The air agitating outlets in the surge tank cemented shut. This was the first difficulty encountered.

The surge tank was discarded. The circulating line was replaced by open wooden launders. The slurry pump was coupled as closely as possible to the overflow from the classifier with a 4-in. flanged rubber coupling. A vertical 4-in. copper line was installed to conduct slurry from the pump to the highest point in the launder distributing system.

In mixing the calcine and zinc sulphate solution more difficulties arose. A crust of cemented slurry soon formed at the top of the turbo-mixer. This cementation was not eliminated by relocating or providing an additional impeller. The mixer was replaced by a mixing launder in which neutral zinc sulphate solution entered through a perforated bottom and was met by the calcine from the top. Subsequently, calcine was dropped into an inclined launder onto a stream of solution. The operation was fairly satisfactory but extremely dusty. Frequent cleaning of the pipe and launders was necessary.

This method was used in the plant until it was found that the slurry could be made satisfactorily by mixing an excess of calcine with spent electrolyte. Replacing the zinc sulphate solution with spent electrolyte made possible the use of a large, vented, bottom-discharge mixing tank, which discharged the slurry continuously through an air lift into the classifier. Mild steel plate and rakes were satisfactory in the classifier with the zinc sulphate-calcine slurry. The use of spent electrolyte introduced soluble copper and resulted in severe corrosion. Stain-

less steel rakes were installed first and eventually all exposed parts of the classifier and other equipment were replaced with stainless steel.

Early in 1950, the launder system was replaced by a stainless steel distribution box with rubber hose lines from the box to the individual leaching tanks.

Now the slurry is made in a stainless steel tank where the calcine is mixed with the acid and discharged through the air lift to the classifier. The feeding of the calcine, spent electrolyte, and iron solution is controlled and proportioned automatically. Adequate suction is provided by a small fume scrubber so that the operation is dust and vapor free. About one third of the leaching takes place in this tank. The cementing problem is minimized by the increase in the solution: solid ratio and the reduction in the amount of free zinc oxide present for cement formation.

Thickener underflow was filtered originally on Moore filters. It was found that these filters were unsatisfactory for the new pulp, because the consistency was such that heavier particles settled out in the filter tanks. This had not been the case when the voluminous silica gel was present. Air agitation was not successful in keeping heavier particles in suspension. The cake picked up on the Moore filter dewatered so fast that it was impossible to transfer it to the wash tank before the cake cracked badly. Further, once cracked, portions of the heavy cake, especially around the bottom of the leaves, fell off. Both of these conditions made satisfactory washing impossible.

Therefore, the thickened pulp was pumped directly to the Eimco filters. Filtration was satisfactory but washing was not. A cake in excess of  $\frac{1}{2}$  in. was necessary for proper discharge. The water-soluble zinc in such a cake was not removed during the washing time available. Residues high in water-soluble zinc were difficult to dry.

An unforeseen condition of the thickened reverse-leach pulp led to a change in the thickener operation. When this pulp has aged more than 48 hr, it becomes extremely viscous and difficult to filter, and there is a retention of zinc sulphate. The filtrate from an aged pulp will contain less zinc than the solution in which it has thickened. The difference is as much as 60 g per liter zinc. It can be recovered by washing the filter cake with water. The first displacement and as high as the first three displacements of liquor in the filter cake, depending on the time the pulp has aged, will contain more zinc than the original filtrate. An aged pulp requires a large amount of water and much time to wash the filter cake free of zinc sulphate, or in other words, more filter capacity for the same amount of solids.

In making the changes outlined to overcome the difficulties encountered, a very satisfactory and workable process has been developed.

### Operations

Calcine, as-received, is fed at a uniform rate from the storage bins into the mixing tank. Return electrolyte is added to maintain a slurry density of about 1.5 sp gr. This density permits classification at 100 mesh. Oversize material is ground in the ball mill and returned to the classifier. A typical screen analysis of the ground slurry is given in Table I. Grinding to smaller particle size does not increase the zinc extraction materially.

Slurry containing 4.5 to 5 tons of equivalent calcine is fed to one of six leaching tanks which will

Table I. Screen Analysis of Ground Slurry

| Mesh | Pct |
|------|-----|
| 35   | Nil |
| 65   | 1   |
| 100  | 3   |
| 150  | 6   |
| 200  | 10  |
| -200 | 80  |

contain a "heel" of return electrolyte just covering the agitator. This is neutralized so rapidly that little or no silica is taken into solution. Slurry addition is timed, 30 min per tank, since the weighing device is set to deliver the calcine for one leach in that time.

Acid containing from 0.5 to 1.0 g per liter iron as ferric sulphate is added to the slurry until a test of the pulp at the top of the tank shows acid to methyl-orange indicator. The acid addition is stopped until the test shows neutral or basic to methyl-orange. Then, more acid is added until a positive test again occurs. This is repeated until the acidity persists for about 3 min, which is the point of maximum zinc extraction, and the leach would be complete except for the presence of ferric sulphate. Precipitation of ferric hydroxide occurs here with the release of some free sulphuric acid which must be neutralized. A small amount of slurry is added. Completeness of iron precipitation is checked with ammonium thiocyanate test papers. Small amounts of ferrous iron are oxidized by compressed air introduced beneath the agitators and dispersed through the leach. The copper required for this reaction originates from the calcine. Ferrous iron occurs only in those calcines which have not been roasted thoroughly.

While satisfactory washing could be attained using a cotton twill filter cover, blinding of the cloth and decreasing filtration rate with time required frequent changes of the cover. In 1948, a nylon filter cover was used for the first time with excellent results. This is a specially woven cloth with tightly twisted yarn in which filtering is only through the fabric openings. The only blinding comes from precipitation of gypsum and this has been largely overcome by the use of low-pressure steam instead of air for the blow-off.

Summed up, the operating difficulties which called for correction because of inability to attain the rated capacity of the plant were:

1. Difficult and slow filtration of the purified solution.
2. Absence of clear overflow from the thickener.
3. Inability to filter and wash residue.
4. Inability to dry residue.
5. Wasteful impounding of residue.
6. Wasteful consumption of sulphuric acid, manganese dioxide, and calcine.

The introduction of "reverse" leaching has made it possible to:

1. Provide an adequate amount of purified solution.
2. Have 8 to 10 ft of clear solution in the secondary thickeners.
3. Filter and wash effectively the entire residue output.
4. Dry all the residue filtered.
5. Stop the impounding of unwashed residue.
6. Cut the consumption of sulphuric acid, manganese dioxide, and calcine.

# Metallurgical Reactions of Fluorides

by Herbert H. Kellogg

Graphs representing the standard free-energy of formation as a function of temperature for 21 fluorides are presented, along with estimated values for the standard free-energy of formation of 20 additional fluorides. A few of the many possible uses of these data in metallurgical calculations are discussed, including the fluorination of oxides, sulphides, and chlorides, and the reduction of metal fluorides.

RECENT papers which have presented free-energy data for oxides, sulphides, chlorides, carbonates, sulphates, and silicates in the form of free energy vs. temperature plots,<sup>1-5</sup> have found important uses in teaching and metallurgical development work. This method of presentation of thermodynamic data serves to make available in readily usable form thermodynamic constants which are scattered throughout the literature, and to show by graphical means the stability relations which exist between the compounds of a given type. It is certainly desirable to have these free-energy-temperature diagrams for as many types of compounds as are of present or potential use in metallurgical processes. Thus, even though there are but few uses of metallic fluorides in extractive metallurgy today, the potential uses of fluorine processes are of great importance and serve as the principal justification of this paper.

Recent developments in the production of fluorocarbons have resulted in vastly improved methods for the production and handling of fluorine and corrosive fluorides, with consequent reduction in costs.<sup>6,7</sup> The extractive metallurgist should no longer overlook possible fluorine processes when development of a new process for a relatively high unit-price metal is being considered.

In a previous paper<sup>8</sup> the author outlined in some detail the importance and use of free-energy data in metallurgical calculations and also discussed the properties of a standard free-energy vs. temperature diagram. The same method of presentation is adopted in this paper, and the reader is referred to the earlier work for explanations of the use of free-energy data.

## Thermodynamic Data

This paper presents standard free-energy vs. temperature diagrams, Figs. 1 and 2, for those fluorides for which the major thermodynamic constants are known. In the calculations of the standard free-energy of formation ( $\Delta G^\circ$ ), values of the enthalpy of formation at 298°K ( $\Delta H^\circ_f$ ) were taken from "Selected Values of Thermodynamic Constants",<sup>8</sup> most of the values of standard entropy at 298°K ( $S^\circ_{298}$ ) were taken from "Selected Values",<sup>8</sup> but in a few cases the values given by Kelley<sup>9</sup> were preferred; data for the phase changes came from "Selected Values" and several of Kelley's publica-

tions;<sup>9-12</sup> and most of the specific-heat data were taken from Kelley.<sup>10</sup> The appendix gives a detailed list of the sources of the data.

As explained in an earlier paper,<sup>8</sup> the accuracy of some of the standard free-energy relationships is not high. An error of  $\pm 1$  kcal at 1000°C is expected in most of the curves of Figs. 1 and 2. The error may be as high as  $\pm 3$  kcal in some of the curves. Rather than attempt to estimate the reliability of each curve, the source of the data used is reported in the appendix, and the reader may compare these data with newer values as they become available.

Figs. 1 and 2 fail to show values for the fluorides of many important metals. In most cases this is because the entropy of the metallic fluoride is unknown. For preliminary calculations it is often useful to have available the best estimate of an unknown datum, rather than no information at all. With this in mind, Table I lists estimated standard free-energy values for a number of important metallic fluorides not included in Figs. 1 and 2. The values reported in Table I were calculated by Brewer et al.<sup>13</sup> and are based on estimated entropy values. The estimated uncertainty of the values for each fluoride were calculated from the uncertainty values given by Brewer<sup>13</sup> for  $\Delta H^\circ$ , and the entropy function.

Table I. Estimated Values of Standard Free Energy of Fluorides\*

| Compound             | Temp. °C |        |        |            | Uncertainty, kcal at |       |
|----------------------|----------|--------|--------|------------|----------------------|-------|
|                      | 25°      | 227°   | 727°   | 1227°      | 227°C                | 727°C |

\* Based on values estimated by Brewer et al.<sup>13</sup> Values are for the solid compounds, except those marked (1), which are for the liquid fluorides. Uncertainty values take into account the uncertainty in  $\Delta S^\circ$  as well as  $\Delta H^\circ$ .

HERBERT H. KELLOGG, Member AIME, is Assistant Professor of Mineral Engineering, Columbia University, New York.

Discussion of this paper, TP 3009 D, may be sent to AIME by April 1, 1951. Manuscript received Sept. 8, 1950. St. Louis Meeting, February 1951.

Fig. 1—Standard free energies of formation for metal fluorides as a function of temperature  $\Delta G^\circ$  between  $-20$  and  $-150$  kcal.

*M, B, S, and T* refer to normal melting, boiling, sublimation, and transition temperatures of the metal fluorides; *M', B', S', and T'* refer to the same phase changes for the metal.

### Metallurgical Applications

**Reduction of Fluorides:** It will be recalled<sup>5</sup> that a free-energy vs. temperature diagram such as given in Figs. 1 and 2, is a quantitative affinity series for the compounds listed, which is valid over the temperature range covered. The most stable fluorides are those with the most negative value of the standard free-energy of formation (the alkali and alkaline-earth fluorides at the bottom of Fig. 2). Since the basis for the values reported on Figs. 1 and 2 is 1 mol of fluorine, the subtraction of the value for one fluoride from that of another fluoride, results in the reaction whereby the latter metal replaces the former fluoride to yield the latter fluoride and the former metal. The standard free-energy for this replacement reaction, at any given temperature, is the algebraic sum of the standard free-energies read from Figs. 1 and 2. A negative value for the standard free-energy of any reaction indicates that the reaction is spontaneous when all of the reactants and products are in their standard states.

The positions of the curves on Figs. 1 and 2 (and the data of Table I) show at a glance the possibilities for hydrogen reduction of any given fluoride. The metallic fluorides whose curves lie above the curve for  $2\text{HF}$  can be reduced to the metal by hydrogen gas under standard conditions. As the temperature increases the reduction by hydrogen becomes more spontaneous.

A fluoride such as  $\text{UF}_6$ , whose curve lies slightly below the  $2\text{HF}$  curve at  $1000^\circ\text{C}$  can be reduced to the metal with hydrogen if the partial pressure of  $\text{H}_2$  is kept high and that of  $\text{HF}$  low, so that the free-energy ( $\Delta G$ ) becomes negative, even though the standard free-energy ( $\Delta G^\circ$ ) is positive (see ref. 5 for details of calculation of  $\Delta G$  from  $\Delta G^\circ$ ). The fluorides whose curves lie far below the  $2\text{HF}$  curve cannot be reduced to the metal by hydrogen under practical conditions.

As with the chlorides, carbon is almost valueless as a reducing agent for metal fluorides. This conclusion is based on the position of the curve for  $\text{CF}_4$ , which lies far above the curves for most of the

Fig. 2—Standard free energies of formation for metal fluorides as a function of temperature  $\Delta G^\circ$  between  $-150$  and  $280$  kcal.

*M, B, S, and T* refer to normal melting, boiling, sublimation, and transition temperatures of the metal fluorides; *M', B', S', and T'* refer to the same phase changes for the metal.

other fluorides. Sulphur, selenium, and tellurium are likewise very poor reducing agents for most of the fluorides.

A metal will act as a reducing agent for another metal fluoride, if the curve for the fluoride of the reducing agent lies below the curve for the fluoride to be reduced. Thus, magnesium metal could be used to reduce  $\text{TiF}_4$ ,  $\text{ZrF}_4$ ,  $\text{SiF}_4$ , etc., in analogy to the Kroll process.<sup>14</sup>

By adjustment of conditions far from the standard states, such as by use of a vacuum process, the direction of many reduction reactions can be reversed. Thus, silicon metal could be used to reduce aluminum fluoride to the metal at  $700^\circ\text{C}$ , even though the curve for  $\text{SiF}_4$  lies above the curve for  $\text{AlF}_3$  and  $\Delta G^\circ$  for the reduction reaction is positive.

$$\Delta G^\circ_{700^\circ\text{C}} = +171,400 - 168,400 = +3,000 \text{ cal}$$

$$K_{700^\circ\text{C}} = 0.212$$

If, for a first approximation, the aluminum and

silicon are assumed to remain as pure metals, then:

$$K_{700^\circ\text{C}} = 0.212 = \frac{P_{\text{SiF}_4}^{1/2} \times 1}{1 \times 1}$$

$$P_{\text{SiF}_4} = 0.045 \text{ atm} = 34 \text{ mm of Hg}$$

If the reaction were carried out in a vacuum retort, and the pressure kept lower than 34 mm of Hg, the reaction would proceed spontaneously from left to right provided the reaction rate was sufficiently great. For more accurate calculations the alloying of aluminum and silicon would have to be considered.

Electrolysis can be used to reduce any of the fluorides to the metal and fluorine. Figs. 1 and 2 show the reversible decomposition voltage for the electrolysis of the pure fluoride to produce pure metal and fluorine at 1 atm pressure. When the fluoride bath is a mixture of fluorides, appropriate activity corrections must be made to obtain the reversible decomposition voltage under nonstandard conditions (see ref. 5).

In any reaction involving several fluorides, the

possible formation of double fluorides, of which cryolite ( $3\text{NaF} \cdot \text{AlF}_3$ ) is an example, must be taken into account. Kroll<sup>15</sup> has reported the relative stability of several double fluorides and has shown their importance in fluorine metallurgy. The formation of a double fluoride has the effect of reducing the activity of the individual fluorides in a degree proportional to the stability of the double fluoride.

### Fluorination of Oxides, Sulphides, and Chlorides

Tables II, III, and IV list standard free-energies for the type reactions:

The negative values for  $\Delta G^\circ$  exhibited by all of the reactions in Tables II, III, and IV, indicate that all oxides, sulphides, and chlorides can be fluorinated by fluorine gas under standard conditions. This conclusion emphasizes the unusual stability of the

fluorides—they are the most stable general class of compounds.

Despite the fact that the metals and oxides are all thermodynamically unstable with respect to fluorine gas, many metals and certain oxides do not react with dry fluorine gas at room temperature and even higher, because of extremely low reaction rate. Dry fluorine can be handled in glass or silica apparatus at room temperature and somewhat above.<sup>6</sup> Dry fluorine does not appreciably attack steel at 200°C or nickel at 600°C.

When fluorinating a sulphide or chloride with an excess of fluorine gas, the reaction will proceed to the formation of  $\text{SF}_6$  and  $\text{ClF}$ , rather than releasing  $\text{S}_2$  and  $\text{Cl}_2$  as indicated in Tables III and IV, provided that the reaction rate for the formation of  $\text{SF}_6$  or  $\text{ClF}$  is sufficient at the temperature in question. Thus, the complete reactions will be:

$\Delta G^\circ$  for reaction (a) will be more negative (the reaction is more spontaneous) than the values reported in Table III by 198 kcal at 500°C and 147 kcal at 1000°C. The value of  $\Delta G^\circ$  for reaction (b) will be more negative than the values reported in Table IV by 53.5 kcal at 500°C and 54.8 kcal at 1000°C.

If a limited amount of fluorine gas is used to fluorinate a metal sulphide or chloride, the metal fluoride will be produced rather than the sulphur fluoride or chlorine fluoride, as indicated by the relative stability of the fluorides on Figs. 1 and 2.

Tables II, III, and IV also serve to show standard free-energies of fluorination of the oxides, sulphides, and chlorides by other fluorides. The standard free-energy of fluorination of an oxide by HF is obtained by subtracting eq 3 (Table II) from the equation for

Table II. Fluorination of Oxides by Fluorine Gas\*

| Number | Reaction                                                                                             | $\Delta G^\circ$ in kilo-calories |        |        |

\* Data for fluorides from Figs. 1 and 2 and Table I. Data for chlorides from Kellogg.<sup>5</sup> Standard states are  $\text{F}_2(\text{g})$  and  $\text{Cl}_2(\text{g})$  at 1 atm, and the forms of the chloride and fluoride which are stable (at 1 atm pressure) at the temperature in question.

† Based on estimated value for the standard free-energy of formation of the fluoride.

the oxide. Thus, for the fluorination of MgO by HF at 500°C, we have:

And for fluorination of MgO by  $\text{FeF}_2$ , we have:

In general, fluorination of an oxide by a fluoride will be spontaneous, under standard conditions, if the equation for the oxide on Table II has a more negative value of  $\Delta G^\circ$ , than does the equation for the fluorinating agent. Thus, the fluorides at the top of Table II are the strongest fluorinating agents.

The free-energy of fluorination of sulphides and chlorides by metal fluorides can be derived from Tables III and IV in a similar manner.

One interesting application of the fluorination of oxides by hydrogen fluoride is afforded by the phosphate processing industry. In the thermal processing of phosphate rock to produce fused tricalcium phosphate, the fluorine content of the rock is driven off as hydrogen fluoride and enters the stack gases. A process for the recovery of the hydrogen fluoride from stack gases has recently been described.<sup>16</sup> The essential feature of the process is the reaction of the HF with a bed of crushed limestone at room temperature. The reaction is:

The standard free-energy of this reaction at 25°C can be obtained by combination of the data of Table II with the data on the decomposition of  $\text{CaCO}_3$  given by Osborn.<sup>4</sup> The result is:

$$\Delta G^\circ_{25^\circ\text{C}} \text{ for reaction (a)} = -28,100 \text{ cal.}$$

The reaction is therefore spontaneous under standard conditions, and the reaction rate is fast enough to allow efficient absorption of the HF.<sup>16</sup>

When producing superphosphate the evolved fluorine is principally in the form of  $\text{SiF}_4$ ,<sup>17</sup> and it is interesting to see whether limestone could be used to absorb this gas. The reaction would be:

Combination of the data of Table II with that of Osborn<sup>4</sup> yields:

$$\Delta G^\circ_{25^\circ\text{C}} \text{ for reaction (b)} = -20,200$$

This reaction is also spontaneous at room temperature; its rate characteristics have not been reported.

### Summary

The uses of fluorine and fluorides in extractive metallurgy today are very few. However, it is reasonable to expect that the increased "know-how" in handling of fluorine and fluorides, the availability of large quantities of fluorine at relatively low prices, and the unusual properties of many of the metallic fluorides will result in new metallurgical processes.

The free-energy values reported in this paper can serve as a valuable tool in any exploratory work in fluorine metallurgy. The importance and use of thermodynamic data in metallurgical calculations have not been discussed in this paper, but will be

found in an earlier paper,<sup>5</sup> or in any textbook on thermodynamics.

## Cobalt Self-Diffusion:

# A Study of the Method Of Decrease in Surface Activity

by R. C. Ruder and

C. E. Birchenall

The method of decrease in surface activity was used to determine the rates of diffusion of  $\text{Co}^{60}$  into cobalt and into nickel. Since the absorption curves for cobalt radiation were quite complex under the conditions of these experiments, the effects of geometry and surface preparation on the diffusion results were investigated. The cobalt self-diffusion coefficients obey the equation

$$D_{\text{Co}}^{\text{Co}} = e^{-61900/RT} \text{ cm}^2 \text{ per sec.}$$

For dilute cobalt diffusing in nickel,

$$D_{\text{Ni}}^{\text{Co}} = 1.46 e^{-68800/RT} \text{ cm}^2 \text{ per sec.}$$

AS part of the general program to measure the self-diffusion and dilute-solution diffusion rates of the iron-group metals, the diffusion coefficients of cobalt into cobalt and nickel have been measured using the radioactive isotope  $\text{Co}^{60}$ . Self-diffusion studies in iron have been previously reported by Birchenall and Mehl.<sup>1</sup> The technique of measurement used was the decrease in surface activity method described by Steigman, Shockley, and Nix.<sup>2</sup> It has been determined that scattering of the measured beta radiation by the specimen matrix is significantly influenced by the condition of the surface and the counting geometry. Accurate diffusion coefficients can be calculated from the activity data provided that the specimens have plane diffusion surfaces and that the absorption properties of the emitted radiation are determined under geometrical

conditions duplicating with external absorbers the absorption and scattering in a thin film at the specimen surface as nearly as possible.

The cobalt used in this research was originally in the form of hydrogen reduced rondels 99.9+ pct pure. The nickel had been prepared by the carbonyl process and was found by spectrographic analysis to contain 0.03 pct Fe, 0.04 pct Co and smaller traces of other metallic elements for a balance purity of 99.9+ pct Ni. Both materials were vacuum melted and cast in rectangular ingots. Specimens  $\frac{7}{8} \times \frac{7}{8} \times \frac{1}{4}$  in. were machined from these ingots. The specimens were then ground to 4-0 emery paper and annealed in hydrogen for at least a day at 1200°C. Some of the specimens were used in preliminary experimentation after which their diffusion faces were machined to remove the radioactive material from the previous diffusion experiments. After grinding, the specimens were polished using an electrolytic lapping technique described by Mazia.<sup>3</sup> This lapping was continued until at least 0.005 in. was removed from the diffusion surface. The final surfaces were metallographically smooth except for a few fine scratches caused by the glass cloth. A large percentage of the area was undisturbed as determined by microscopic examination.

The grain diameters of the diffusion specimens varied from 0.1 to 5 mm. There were no effects due to grain boundary diffusion in the experiments

R. C. RUDER, Pigments Dept., E. I. duPont de Nemours and Co., Wilmington, Del., was formerly Graduate Student, Carnegie Institute of Technology; and C. E. BIRCHENALL, Member AIME, is Member of Staff, Metals Research Lab, Carnegie Institute of Technology, Pittsburgh.

Discussion of this paper, TP 3004 E, may be sent (2 copies) to AIME by April 1, 1951. Manuscript, Oct. 16, 1950, revision Dec. 13, 1950. St. Louis Meeting, February 1951.

This paper represents part of a thesis submitted by R. C. Ruder in partial fulfillment of requirements for the degree of Doctor of Science to the Graduate Committee of the Carnegie Institute of Technology.

reported here. Probably none should be expected for the grain sizes and temperatures employed.

Cobalt, containing radioactive  $\text{Co}^{60}$ , was plated on the diffusion surfaces from a cobalt sulphate solution made slightly basic with ammonium hydroxide. From specific activity calculations the plated film was of the order of  $10^{-7}$  cm thick. The active cobalt was removed from the edges of the specimens and from the diffusion surfaces for a distance of at least  $\frac{1}{8}$  in. from the edge. Each diffusion experiment consisted of two specimens placed in an iron boat with their diffusion faces together in order to minimize the loss of the active cobalt through evaporation during the high-temperature anneal. Autoradiographs were made of the diffusion surfaces before and after the diffusion anneals. There was no evidence of any change in the surface distribution of the activity due either to evaporation or surface diffusion. Lateral diffusion was too small to produce a significant change in geometry.

The diffusion anneals were carried out in an atmosphere of hydrogen from which oxygen was removed by hot platinized asbestos, followed by drying over activated alumina. In addition, the presence of powdered iron and the iron of the supporting boat removed the final traces of oxygen in the furnace tube. There was no visible oxidation of the diffusion specimens. The temperature was automatically controlled to  $\pm 2^\circ\text{C}$ . In addition, the furnace temperature close to the specimens was checked frequently during the diffusion experiments. The temperature of the specimens was recorded during the heating and cooling of the furnaces, and appropriate correction was made if there was appreciable diffusion occurring during these periods.

The specimens, having nearly equal activities, were counted before and after the diffusion anneals using an argon filled self-quenching tube mounted in a lead counting safe. Counting was continued for times long enough to reduce the statistical counting error well below 1 pct. Relative counting rates were calculated with reference to a standard specimen which was counted frequently during the activity measurements. Appropriate correction was made for background and coincidence errors. At least three counts were made on each specimen to reduce systematic errors in counting rate due to climatic conditions. Agreement within 1 pct was considered satisfactory. Absorption measurements, using nickel, aluminum, and cobalt absorbers, were made on individual specimens before and after diffusion and under various geometric conditions. Details will be considered later.

### Calculation of Diffusion Coefficient

Due to the form of the absorption curve, it is impossible to use an analytical method of computing the diffusion coefficient. A graphical integration was required. The diffusion of an infinitely thin layer of one atomic species into a semi-infinite solid of another may be represented by a function of the form:

$$C = \frac{C_0}{\sqrt{\pi Dt}} e^{-\frac{x^2}{4Dt}}$$

which is the solution of Fick's law appropriate to the boundary conditions, where  $C$  is the concentration of the first species of atom at a distance  $x$  from the diffusion interface.  $C_0$  is the total amount of the first species.  $D$  is the diffusion coefficient, and  $t$

Fig. 1—Temperature dependence of diffusion coefficients for cobalt self-diffusion and for dilute cobalt diffusing in nickel.

is the time of the diffusion anneal. The distribution in  $x$  is therefore determined by the product  $Dt$ . The radiation detected at the surface of the specimen after diffusion from the active material at a distance  $x$  from the surface is obtained from the experimentally determined absorption curve. The ratio of the activities after and before diffusion is therefore the integral from the diffusion interface to a point effectively at an infinite distance into the specimen of the product of the concentration-distance function and the absorption-distance function, divided by the integral of the concentration-distance function. Since the activity ratio is a function of the  $Dt$  product, this graphical process was carried out for a number of  $Dt$  products, and the resulting function of activity ratio vs.  $Dt$  was used to calculate the diffusion coefficient by interpolation. Since this function is appropriate to the tracer and geometry used in these experiments only, it is not presented.

The results of these experiments are given in Fig. 1. The standard deviation of the plotted points from the best least square straight line is about 15 pct, which from calculated errors arising from the observed statistical distribution of the counting rates, errors in absorption measurement and variations in temperature measurement, may be considered satisfactory. For cobalt self-diffusion:

$$D = 0.032 \exp \left( \frac{61.9 \pm 3.5}{RT} \right) \text{ cm}^2 \text{ per sec}$$

while for very dilute cobalt diffusing into nickel:

$$D = 1.46 \exp \left( \frac{68.3 \pm 2.0}{RT} \right) \text{ cm}^2 \text{ per sec.}$$

Here the activation energies are expressed in kcal

Fig. 2—Ratio of activity of a point source of  $\text{Co}^{60}$  under an absorber which makes an angle  $\theta$  with the horizontal plane to the activity of the same source under no absorber.

An exponential correction has been applied for the effectively greater thickness of the absorber due to rotation.

per mol. Cobalt does not show evidence of a change in the diffusion behavior at the Curie point. Nor is there a change at any other temperature in the measured range which might be considered as evidence of a high-temperature phase transformation.

### Absorption and Scattering of Beta Particles\*

An understanding of absorption and scattering processes is critical for the evaluation of diffusion data by the method of decrease in surface activity. Novey and Elliott<sup>5</sup> and Burt<sup>6</sup> found maxima in absorption curves when the source was some distance from the detector. The latter also found that the maxima disappeared if the absorbers were placed close to the counting tube rather than close to the source. Willard and Johnston<sup>7</sup> studied the effect of moving an absorber from tube window toward the source using both randomly directed and collimated radiation. The 1.69 mev. maximum energy beta radiation from  $\text{P}^{32}$  and the 1.1 and 1.3 mev. gamma rays from  $\text{Co}^{60}$  were used. When the radiation was collimated to allow detection of only those rays going directly from source to counter, the effect of moving the absorber from the tube toward the source was to decrease the counting rate for both gamma and beta radiation, though the effect was much stronger for betas. When the collimator was removed, permitting detection of particles scattered into the solid angle subtended by the tube although their original directions lay outside that angle, the effect of moving the absorber from the tube toward the source was to increase the counting rate about the same amount for both beta and gamma radiations.

These experiments rule out the possibility that the effect could be caused by the creation of secondary

radiation and give preliminary indication that the scattering effects are large and significant. The effects could be described in terms of a change in the angular distribution of the radiation as it passes through absorber which also acts as a scattering source. This change in angular distribution would be one in which the component of intensity of the radiation perpendicular to the plane of the absorber is increased at the expense of the component parallel to the absorber plane.

In order to study this angular distribution change as a function of absorber thickness for both front and back scattering, a point source of  $\text{Co}^{60}$  radiation was placed at the center of a very thin Formvar film mounted in a 1-in. diam hole in a thin aluminum sheet. Absorbers could be attached on either side of the radiation source, and the sheet and absorbers could be rotated with respect to the counter. Measurements were made only to  $60^\circ$  on either side of the original horizontal position to avoid possible effects of scattering by the supporting plate and absorber holders. The point source was on the axis of rotation.

As the angle was increased, the effective absorber thickness increased such that if the angle between the normal to the absorber plane and the direction of the detector was  $\theta$ , the effective thickness was  $x \sec \theta$ , where  $x$  was the sheet thickness. From the observation that when absorption measurements were made with the source and absorber close to the tube window the absorption was approximately exponential, correction for this increase in thickness was made.

Due to the fact that the active source had to be

Fig. 3—Effect of counting geometry on the absorption curves obtained on diffusion disks with  $\text{Co}^{60}$  activity on the surface.

\* We were unaware at the time this paper was submitted for publication of the experimental determination of the angular distribution of absorbed  $\text{P}^{32}$  radiation performed by Yaffe and Justus (L. Yaffe and K. M. Justus: *Journal Chem. Soc., London, Supplementary Issue No. 2, 1949*). It is most interesting to have confirming evidence of his anisotropy with beta radiation from a different source. Our conclusion that back scattering is isotropic is confirmed by these authors only for thin back scatterers. Their results show an increase in anisotropy as the back scatterer becomes thicker. However, as this anisotropy is small compared to the forward scattering anisotropy, the basic argument used in our paper is still valid.

mixed with a small amount of rubber cement to fix the position on the Formvar film, there was a small and irregular variation in the distribution of the radiation. However, the results of the angular distribution measurement shown in Fig. 2 give the ratio of the activities with and without absorber for each position and this irregularity cancels out. The top curve is the result of the back-scattering measurements while the four lower curves give the results of forward scattering for increasing absorber thicknesses. The back-scattering process shows no variation in angular distribution caused by the presence of the backing absorber. The forward-scattering curves show that the effect is greatest for the thinner absorbers and becomes less as the absorber thickness is increased.

On the basis of these measurements, it is possible to understand the dependence of the absorption measurements on the counting geometry. For some solid angle comprising a cone with the axis of rotation normal to the absorber, the number of detected particles will be proportionately greater than were originally in that solid angle before the scattering process. For regions outside of this solid angle, the scattering process will cause a relative depletion in the number of particles. If the counting tube is situated at such a distance that it detects only this critical solid angle, or part of it, the relative counting rate will increase as the absorber thickness increases. However, as Fig. 2 shows that the change in angular distribution becomes less as the absorber thickness increases, the decrease in the counting rates caused by the absorption processes becomes the important factor and the absorption curve becomes more nearly characteristic of the absorption processes alone. If the specimen is located closer to the counting tube, the region detected will include an increasing amount of the loss region and the net effects of scattering are more nearly cancelled out. The optimum geometry is obviously obtained by internal sample counting. If this is impossible, the sample should be brought as close to the tube as conditions permit.

In diffusion measurements the sample itself acts as absorber and scatterer. Therefore it is necessary to measure absorption curves with the absorber as close to the sample as possible to reproduce this condition. The curves in Fig. 3 illustrate these effects. The first counting shelf was located at a distance of 0.729 cm from the tube window while the second shelf was located at a distance of 3.64 cm. The lower curve shows the effect of placing the absorber on the first shelf and the specimen on the second. The lowering of this curve is caused by the collimation of the incident beam by the aluminum shelf which supported the absorber.

### Effect of Surface Irregularities

Because of the scattering of electrons, detailed consideration of the diffusion process at the surface of the specimen is necessary. These irregularities may be due to abraiding, chemical etching, or thermal etching of the surface during the diffusion anneals. The detailed consideration for any particular case would of course depend on the exact form of the surface. However, the general situation may be visualized by consideration of a simple case which should provide the worst scattering effects. This will consist of triangular grooves of such steepness that the normals to the microsurface form angles with the normal to the macrosurface which

Fig. 4—Iso-concentration lines for different degrees of diffusion penetration into an irregular surface.

exceed the angle of increased activity due to scattering. Analytical solution of the diffusion equation even for this simplified case is difficult, but a qualitative consideration of the diffusion into this type of surface will suffice.

As the active atoms first diffuse into the base metal, iso-concentration lines will originally follow the microsurfaces. As diffusion progresses, the iso-concentration lines will begin to approximate the macrosurface and will become essentially parallel to it when the diffusion distances are large with respect to the surface irregularities. This sequence of events is shown schematically in Fig. 4. This, together with consideration of the scattering behavior, will permit discussion of the effects of the surface irregularities on the emitted radiation. The initial active film which is of the order of atomic dimensions will not scatter the radiation to an appreciable extent. Further, backscattering from the irregular surface will not cause a change in the angular distribution of the radiation. Therefore, the deposited layer will emit isotropically. As the active atoms diffuse into the surface, there will be a comparatively large decrease in the measured activity since the radiation will be scattered away from the detector in the direction of the normals to the microsurfaces. As diffusion progresses, the directions of maximum intensity will move from the normals of the microsurfaces in the direction of the normal to the macrosurface and will eventually coincide with it.

The correctness of this picture may be checked experimentally in at least three ways: First, by comparison of diffusion coefficients from specimens with differing surfaces. Three series of experiments were performed which may be compared by consideration of the diffusion coefficients at the same temperature, 1000°C. The first series was abraided with 4-0 emery paper; the second was etched in hot concentrated hydrochloric acid; and the third was electrolytically lapped. This is a sequence of increasing smoothness. The comparison of the apparent cobalt self-diffusion coefficients at 1000°C, calculated on the assumption of plane surfaces, is given in Table I.

It will be observed that the rougher surfaces give the higher rates of diffusion. In order to evaluate the significance of the results, it is necessary to remember that the absorption curves used in the calculation of the diffusion coefficients represent the combined effects of absorption and scattering in a plane parallel film of metal of radiation from an emitting source where the angular distribution of the radiation is isotropic. If there is any scattering of the radiation away from the normal to the macro-

surface, this will be equivalent to higher absorption in the specimen, indicating a greater depth of penetration and a higher rate of diffusion. As diffusion into polished surfaces most nearly duplicates the assumed conditions only the work done on these surfaces is presented as representing the true diffusion rates.†

The second check on the validity of the above picture is the dependence of the calculated diffusion

coefficients on the amount of diffusion as measured by the ratio of activity of the specimens after and before diffusion for specimens with irregular surfaces. As there is an initial scattering of the radiation away from the normal to the macrosurface which becomes less as diffusion proceeds, the calculated diffusion coefficients should be high after short times and decrease as the activity ratio decreases. This conclusion was experimentally verified by interrupting the diffusion process at various times for activity measurements. Table II shows the results on a cobalt specimen pair with etched surfaces diffused for increasing times at 1000°C.

The third check is provided by comparison of diffusion coefficients calculated from activity ratios measured at different distances from the tube using

† After this manuscript was prepared a note on cobalt self-diffusion appeared: F. C. Nix and F. E. Jaumot, Jr., *Physical Review* (1950) 80, 119L. Their equation,  $D = 0.367 e^{-67000/RT}$  cm<sup>2</sup> per sec for points at 1050°, 1150°, 1250°C., corresponds to higher diffusion coefficients than those reported here, but lower than unreported values obtained on ground (4-0 emery paper) and etched surfaces. In the absence of a description of their surface preparation, no conclusions may be drawn.

absorption measurements made at those distances. Two cobalt specimens were diffused at 970°C for  $4.93 \times 10^6$  sec. The activity ratios and calculated diffusion coefficients are shown in Table III.

Although the measured activity ratios are quite different using the two geometries, the diffusion coefficients calculated using the absorption curve appropriate to each geometry show good agreement.

Much work remains to be done in order to fully understand and interpret this scattering effect. As only one radiation source was used in these experiments, the effect of such variables as particle energy is not known. However, as this method of measuring diffusion coefficients provides a more rapid and potentially more accurate technique for low diffusion rates than the conventional sectioning methods, further investigation of these scattering phenomena should be of great interest.

### Summary

The cobalt self-diffusion coefficients have been measured using the decrease in surface activity method and found to satisfy the equation:

$$D = 0.032 \exp \left( \frac{61.9 \pm 3.5}{RT} \right) \text{ cm}^2 \text{ per sec}$$

The diffusion coefficients for very dilute cobalt in nickel measured in the same way have been found to satisfy the equation:

$$D = 1.46 \exp \left( \frac{68.3 \pm 2.0}{RT} \right) \text{ cm}^2 \text{ per sec}$$

(The activation energies are in kcal per mol.)

Scattering of the beta radiation was measured and found to influence the calculated diffusion coefficients to a very significant extent.

### Acknowledgments

The authors wish to express their gratitude to the Office of Naval Research for the support of this work, to R. F. Mehl for numerous discussions during the course of these studies, and to L. F. Gronholz and J. Ferrin for much of the radioactive counting. The Co<sup>60</sup> used in these experiments was obtained from the Isotopes Division, U. S. Atomic Energy Commission.

# Formation and Behavior of Subboundaries in Silicon Iron Crystals

by C. G. Dunn and F. W. Daniels

IN recent publications<sup>1-5</sup> the existence and behavior of subgrain boundaries in high-purity metals has been clearly brought to light. Lacombe and Beaujard<sup>1</sup> by means of special etching methods disclosed in polycrystalline sheets of aluminum the existence of substructures differing in orientation by small amounts (about  $\frac{1}{4}^\circ$ ). Boundaries of these structures at relatively high temperatures had the remarkable property of moving about while the ordinary boundaries remained stationary. Cahn<sup>2</sup> also observed substructures in bent and annealed single crystals of aluminum, zinc, magnesium, and rock salt. The position of subboundaries could be explained in terms of a *dislocation mechanism of polygonization* in which dislocations move into lines at right angles to the bent glide planes thereby relieving elastic stresses in these planes. Guinier and Tennevin<sup>3, 4</sup> disclosed the further interesting feature that polygonized structures coarsened significantly upon prolonged annealing.

Somewhat similar subgrain phenomena have been observed in silicon iron of commercial purity. Although some evidence for the development of macro-mosaic structures in silicon iron already has been reported by one of the authors<sup>6, 7</sup> under the phenomenological term "crystal recovery," much better evidence recently has been obtained due to improved etching techniques. In addition, phenomena regarding structural changes have been uncovered.

The present investigation is divided into three parts: (1) The phenomenon of Laue spot sharpening on annealing cold-rolled crystals, (2) the phenomena of polygonization and subgrain coarsening

Fig. 1—Stereographic projection of {100} cube poles and the probable most active <111> slip direction. Open circles give original orientation and solid circles the orientation after cold rolling.

in (a) bent single crystals and (b) cold-rolled crystals, and (3) boundary and subboundary interactions.

## Procedure

The material used in the present investigation was high-grade commercial silicon iron sheet of nominal composition, 3.3 pct Si, 0.004 C, 0.011 P, 0.010 S, 0.04 Mn, 0.01 Al, 0.04 Cu, 0.01 Sn. Large single crystals of this material were prepared for cold-rolling or bending as scheduled. Cold-rolling of 12 pct was carried out on a laboratory 8-in. diam rolling mill. The bending deformations were performed by pressing the crystals between a solid

Fig. 2—Illustrative Laue patterns to show Laue spot sharpening. a (left)—Specimen as cold rolled. b (right)—After 48 hr at 1400°C.

round bar and a mating half cylinder, both heavily greased. Individual specimens were cut from the deformed crystals, and the cut edges were deeply etched prior to annealing. Laue photographs were made using 40-kv tungsten radiation. The technique used to disclose the various subboundaries was an electropolish and electroetch in a bath of chrome-acetic acid.<sup>8</sup> The anodic polishing done at 22 v was immediately followed by etching at a reduced voltage, which was dependent upon the nature of the subboundaries.

## Phenomenon of Laue Spot Sharpening on Annealing Cold-Rolled Crystals

Fig. 1 gives the initial and final orientations of the specimens cold-rolled 12 pct. Each specimen was annealed at a temperature and for a time which caused significant structural changes as evidenced by alterations in Laue patterns.

Representative Laue patterns<sup>9</sup> and micrographs showing the essential changes are given in Figs. 2, 3, and 4. The essential points to be derived from these illustrations follow:

1. Annealing at 950°C clearly develops a substructure with the orientation of the cold-rolled specimen.

2. The subboundaries formed obviously separate regions of nearly the same orientation. Some of the subboundaries appear as a sequence of dots similar to those observed in aluminum by Lacombe and Beaujard,<sup>1</sup> but whether this is due to extremely small differences in orientation is not known at present.

3. The substructure coarsens upon prolonged annealing.

4. Prolonged annealing also causes a decrease in orientation spread according to Laue spot sharpening.

C. G. DUNN, Member AIME, is Research Physicist, and F. W. DANIELS, is Metallurgist, General Electric Co., Pittsfield, Mass.

Discussion of this paper, TP 3005 E, may be sent (2 copies) to AIME by April 1, 1951. Manuscript, Oct. 9, 1950. St. Louis Meeting, February 1951.

5. These alterations in the Laue photographs and the accompanying coarsening of the structure may be interpreted to mean that a *selective* growth of subgrains has occurred. Stated another way subgrains with orientations further removed from the average orientation of the composite are consumed by those closer in orientation to the average.

### Phenomena of Polygonization and Subgrain Coarsening

**Bent Single Crystals:** A number of bent specimens were prepared from a large single crystal 0.025 in. thick. Fig. 5 gives the pertinent crystallographic directions and the axis of bending which coincides with a  $[1\bar{2}1]$  direction. Preliminary X-ray and micrographic data for annealed specimens disclosed that high-temperature annealing produced many lamellar shaped subgrains within each original crystal. X-ray data, for example, disclosed that each Laue spot changed to a discrete set of smaller spots (a fine structure) covering the original orientation range. Fig. 6 shows such a set obtained by using an X-ray camera in a focusing position to obtain maximum sharpness of the spots. The average difference in orientation from these patterns is (a)  $0.22^\circ$  or (b)  $0.23^\circ$ . Fig. 7 shows the accompanying microstructure in a plane perpendicular to the axis of bending, see Fig. 5. The structure was disclosed by a thermal etch—a method often superior to ordinary chemical etches but far inferior to the chrome-acetic acid electroetch. One may speak of the foregoing structure as polygonized.\*

Regarding the boundary orientations, the present boundaries lie approximately  $90^\circ$  to the  $[111]$  direction as shown in Fig. 7, and this raises a question regarding possible crystallographic relationships between boundary directions and active slip planes

as predicted by the dislocation mechanism of polygonization.

To check the crystallographic relationships for formation of the new boundaries, visible traces of active slip planes were obtained before annealing and compared with the boundaries formed in a subsequent anneal. Fig. 8a shows that there are two sets of slip lines corresponding to slip on the  $(10\bar{1})$  and  $(011)$  planes. Fig. 8b shows the final subboundary for the identical area after a high-temperature anneal (subboundaries are very faint) and Fig. 8c also shows a representative structure at this point. Comparison of the photographs discloses that the boundary lines are perpendicular to the  $(10\bar{1})$  slip lines which, in this case, coincide with the  $[111]$  direction. Disregarding slip on  $(011)$  planes, the results agree well with those predicted on the basis of movement of dislocations ( $[\bar{1}21]$ -edge dislocations which are perpendicular to the plane of the microsection) until they form subgrain boundaries at  $90^\circ$  to the  $(10\bar{1})$  slip plane (this plane is in the maximum shear position and, therefore, probably the most active one during plastic bending). More will be said about this later.

\* The descriptive term *polygonized* was supplied by E. Orowan and R. W. Cahn to indicate that the line of atoms in a specific crystallographic direction taken in each subgrain along the arc of the bend forms part of a polygon. Also if the lattice is elastically bent prior to annealing, there is no polygonized state until a subdivision into unbent units occurs. This breakup into unbent units is called *polygonization*.

b (bottom)—0.010 in pinhole system.

Fig. 7 (left)—Microstructure of specimen P5 after 22 hr 1300°C anneal in argon. Thermal etch. X200.

Other specimens were used to investigate the early stages of formation of the polygonized structure and also the effect of amount of bending. Three parts (P2, P3, and P4) of the original crystal were bent to radii of 21/32, 3/8, and 3/32 in., respectively. Each part was further divided into a number of specimens for various treatments. Fig. 9 shows the microstructure of some P3 specimens before and after heat treatment, the latter three being a sequence on a single specimen. Another P3 specimen of importance but not photographed was annealed 15 min at 775°C.

The micrographs disclose a coarsening of the substructure as well as the formation of subboundaries 90° to the direction of (101) slip lines. The slip lines here are revealed after sectioning and therefore are representative of interior regions of the bent crystal. These lines are not called subboundaries. The subboundaries initially formed are very wavy and often appear to terminate in the matrix; only later in the annealing do they become relatively straight. Some areas in the 775°C annealed specimen disclosed no subboundaries, other areas did. Among these subboundaries there were some that

Fig. 8 (above)—Microstructure of bent specimen P1, 21/32 in. radius, before and after annealing.

extended only from one slip line to another.

Figs. 10 and 11 show micrographs for the P2 and P4 series, respectively. P2 appears incompletely transformed after 10 min at 950°C. Lines that coincide with the original slip lines are still present and the structure in general is quite heterogeneous. The increase in subgrain size on prolonged annealing at 950°C is very striking. Specimen P4 reacted to the 950°C anneals in somewhat similar fashion, the coarsening, however, being less pronounced. The 1300°C treatment converted P4 to a single crystal of new orientation. Unlike the subgrains, which had a common [121] direction, this new crystal had a different orientation and therefore could not have been one of the observed subgrains which had grown at the expense of others. The origin of this grain is beyond the scope of the present paper; it

Electro etch. X200. Reduced approximately 33 pct for reproduction. *a* (upper left)—Bent and sectioned to show slip lines. *b* (upper right)—After 10 min at 950°C. *c* (lower left)—After 24 hr at 950°C. *d* (lower right)—After 4 hr at 1300°C.

is more properly dealt with under the phenomenon of primary recrystallization.

X-ray data representing early and late stages of the treatments are shown in Figs. 12 to 14. Annealing for 10 min at 950°C appears to have produced a change in the uniformity of the Laue spot for specimen P3. No such change, however, is apparent for P2, and a nonuniform Laue spot for specimen P4 is present both before and after annealing. It might be concluded from these X-ray data that specimen P4 was partly polygonized before annealing, that specimen P3 polygonized some in the 10-min 950°C anneal, and that P2 did not polygonize at all in the same anneal. However, the micrographic data indicate degrees of polygonization not resolvable by the present X-ray technique. No refined technique such as that employed by Guinier<sup>8</sup> was attempted, however, since the micrographs were entirely satisfactory for revealing early structures. After appreciable subgrain coarsening, ordinary X-ray techniques sufficed to determine the nature of the substructure.

Table I. Average Width of Subgrains in Microns

| Anneal         | P2   | P3   | P4  | P5   |
|----------------|------|------|-----|------|
| 10 min at 950° | 3.5  | 5.1  | 2.2 |      |
| 24 hr at 950°  | 18.3 | 13.7 | 3.7 |      |
| 4 hr at 1300°  | 42.5 | 35.3 |     |      |
| 22 hr at 1300° |      |      |     | 39.5 |

Table II. Angle of Separation  $\theta$  in Degrees

| Anneal         | P2    | P3    | P4    | P5   |
|----------------|-------|-------|-------|------|
| 10 min at 950° | 0.017 | 0.043 | 0.075 |      |
| 24 hr at 950°  | 0.088 | 0.12  | 0.13  |      |
| 4 hr at 1300°  | 0.21  | 0.30  |       | 0.19 |

The widths of lamellar subgrains were measured to obtain the values given in Table I.

Using an angle of 45° for the directions of the boundaries and assuming a progressive rotation of the subgrains, geometry considerations indicate that the average angle between adjacent lamellae should be, to a good approximation:

$$\theta = \frac{W \times 57.3}{R (0.707)} \quad [1]$$

where  $W$  is the average width of the subgrains and  $R$  is the radius of bend. With this equation and the foregoing data the values given in Table II were obtained.

The largest subgrains were approximately double the average size. The values of 0.19° for specimen P5 and 0.21° for P2 obtained from eq 1 agree well with the X-ray diffraction value of 0.22° or 0.23° given previously for specimen P5. This agreement justifies the assumption of a progressive rotation of the subgrains *after coarsening*. On the other hand it does not prove that the *initial subgrains* actually differed in orientation by 1' to 4' (0.02° to 0.07°) as calculated in Table II.

**Cold-rolled Crystals:** In Fig. 4a, there are narrow lamellae in certain regions of the microstructure, which look very similar to the lamellae developed in bent specimens. The crystallographic relationship obtained from Figs. 1 and 4a show that the parallel boundary lines are approximately 90° to a  $\langle 111 \rangle$  direction, S.D., which should have been active according to the orientation change produced during deformation. This part of the transformation, therefore, appears to be identical with that occurring in bent specimens and suggests that local regions of the lattice were bent during cold-rolling.

The structure in such local regions after annealing, therefore, may be described as polygonized. As the structure coarsens, however, it has less and less the characteristics of a polygonized one, not because the lamellar structures vanish but because larger units no longer have simple relationships in an orientation sequence. The coarsened structure is probably better described as macromosaic. At the stage of coarsening represented by Figs. 3d and 4b, however, there still are present a number of parallel boundaries in the direction of the original polygonized lines and this indicates some persistence of the structure. A similar situation appears to have been the case in an example of crystal recovery cited by Dunn<sup>7</sup> (see his Figs. 8, 9, and 10), because if  $\langle 111 \rangle$  directions are added to Fig. 10, they fall roughly  $90^\circ$  to the subboundaries of the micrograph.

### Boundary and Subboundary Interactions

The results of boundary and subboundary interactions reported in this section are largely of a preliminary and qualitative nature.

The simplest example of interaction involves two grains, one in a strain free state, the other containing considerable substructure as shown in Fig. 15, for example. As in the case of specimen P4 described previously, grain A is the result of primary recrystallization but, in this example, has not completely consumed the polygonized grain. Although primary recrystallization may provide suitable examples of interaction as illustrated above, greater control of the variables is possible if two-grain specimens are made in another way.

In the controlled method one grain is grown until about half of a fine-grained specimen is transformed. The entire specimen is then bent and the untransformed area is converted to a second grain. In this second step the first grain undergoes polygonization. A Laue photograph, such as Fig. 16a taken at the grain boundary of a completed specimen, would show one grain in the strained condition and the other strain free as evidenced by Laue asterism and sharp Laue spots, respectively. Micrographs of such specimens, however, show that the strained grains actually are polygonized.

When a specimen is annealed at temperatures of  $1200^\circ$  to  $1300^\circ\text{C}$ , the strain free grain grows at the expense of the polygonized grain, with parts of the boundary often moving away from their centers of curvature. In other words the situation appears to be similar to that of growth into a strained matrix. Since the surface tensions of the subboundaries no doubt are small, one should expect near  $180^\circ$  grain boundary angles at boundary and subboundary junctions and consequently little evidence for subboundary driving energy from the geometry of the boundary, see Fig. 15. Nevertheless, the major driving energy in the present illustrations reasonably resides at the subboundaries. The ideas of Bragg,<sup>9</sup> Burgers,<sup>10</sup> and Smith<sup>11</sup> on subboundaries and subboundary energies are particularly pertinent to this view although some of the ideas apply more specifically to the cold-worked state.

A more complicated type of interaction involves two grains each with subboundaries. For example, a two-grain specimen may be cold rolled and annealed with each part behaving as in the early illustration—that is, developing substructures, which coarsen while the subboundaries apparently balance out at the boundary. Such coarsening of a substructure was of course not observed in previously pub-

Fig. 10—Microstructure of bent specimens P2, 21/32 in. radius, after various anneals.

lished work on silicon iron<sup>6,7</sup> where the ordinary boundaries remained essentially unchanged during Laue spot sharpening. However, since the conditions of deformation and annealing were similar to those of the present work, it is believed that subgrain coarsening did occur and was responsible for the observed sharpening of Laue spots.

Some cases have been observed in cold-rolled specimens where one grain grows at the expense of the other (a case of unbalanced subboundaries). Examination of the area swept by the grain boundary usually discloses the presence of subboundaries, which continue back to the original position of the boundary. This means that subboundaries are "pulled along" with the boundary as it moves. Some of the subboundaries produced in this way separate regions differing in orientation by a degree or two. The appearance of grain boundaries in the strain-induced grain boundary migration experiments in high-purity aluminum of Beck and Sperry<sup>12</sup> indicate that subboundaries no doubt would be formed

Fig. 11—Microstructure of bent specimens P4, 3/32 in. radius, after various anneals. Electro etch. X200. a (left)—After 10 min at 950°C. b (right)—After 24 hr at 950°C.

similarly in the traversed areas. It is, therefore, not very surprising that the strain-anneal method for producing large crystals in high-purity aluminum often produces rather imperfect crystals as reported by Lacombe.<sup>18</sup>

That an unbalance of subboundaries adjacent to an ordinary boundary will promote migration of the latter can readily be shown. To illustrate, if the specimen of Fig. 16a is again bent and polygonized (see Fig. 16b), the resulting two grains differ in their subboundary energy per unit volume and the one that is least bent (lowest energy in this case) will grow at the expense of the other. In a 1300°C, 3-hr anneal the boundary for this case actually moved a small amount. X-ray and micrographic data disclosed that the subboundaries moved along with the grain boundary, altering but not removing polygonization in the traversed area. The polygonized state in the area traversed by the boundary clearly did not originate through a *dislocation-mechanism of polygonization* as described by Cahn; rather it arose from growth of a polygonized region adjacent to it. Since this phenomenon may occur under less controlled conditions, it follows that simple growth processes may play a role in the development of polygonized areas. Alterations in the substructure and thus alterations in the detailed picture of a polygonized state through growth of the subgrains have, of course, already been discussed.

### Energetics of Boundary and Subboundary Migration

**Boundary Migration:** The grain boundary energy equation of Shockley and Read<sup>14</sup> should apply especially well to subboundaries, because the orientation differences involved are very small. The equation is:

$$E = E_0 \theta (A - \ln \theta) \quad [2]$$

where  $E$  is the energy per unit area of grain boundary,  $\theta$  is the difference in crystal orientation, and  $E_0$  and  $A$  are approximately constants.

Assuming eq 2 applies and that the energy reaches a maximum at  $\theta$  equal to 30°, it follows that the energy in a subboundary of coarsend substructure ( $\theta$  equal to 0.2°) is about 1/25 the maximum value (i.e., approximately 1/25 that of an ordinary boundary). With smaller  $\theta$ 's the energy would be less than this.

The energy per unit volume, or the driving force, is more important for boundary migration. Assuming a uniform lamellar substructure of width  $w$  equal to  $40\mu$  and a  $\theta$  value of 0.2°, it follows that the energy per unit volume would be:

$$\frac{E(0.2^\circ)}{w} = \frac{E_{30}}{25w} = 10E_{30} \quad [3]$$

This value of available driving force is approximately the same as that obtained in grain-growth experiments on two-grain specimens of silicon iron carried out at temperatures of 1300° to 1400°C and appears to be near a lower limit for ordinary grain-boundary migration at these temperatures.<sup>15</sup> An estimate of the absolute value of this energy per unit volume indicates that it would be about  $10^{-6}$  that measured for heavily cold worked iron.<sup>†</sup>

Growth of a grain at the expense of another because of subboundary energy in one of them, as was illustrated in Fig. 15, would be expected to be slow, therefore, according to these estimates of available driving force.

A more general energy relationship for lamellar subgrains can be written in terms of the orientation difference  $\theta$  and the radius of bend  $R$ , since these quantities together with the boundary direction  $\phi$  determine the width of the subgrains. From eqs 1 and 2 it follows that:

$$\text{Energy per unit volume} = \frac{E_0 (A - \ln \theta)}{R \cos \phi} \quad [4]$$

where  $\phi$  generally is near 45°.

According to this equation the average driving force for boundary migration decreases with increasing values of  $\theta$  and  $R$  indicating: (1) That subgrain coarsening lowers the total energy as it should and (2) with constant  $\theta$ , less bending of the lattice leads to less energy, which also is reasonable.

When boundary migration involves subboundaries on both sides of the boundary, the driving force is

<sup>†</sup> Perhaps significant in this connection is some unpublished work on microhardness vs. crystal recovery in silicon iron crystals which has shown almost 100 pct removal of work hardening for equivalent anneals to those producing polygonization in the present investigation.

Fig. 12 (left)—Enlarged Laue spot of specimen P2.

a (top)—As-bent. b (center)—After 10 min at 950°C. c (bottom)—After 4 hr at 1300°C.

obtained as a difference in subboundary energy per unit volume. If this difference is zero, there is no net driving force to move the grain boundary. Instances may occur where the difference is so small that little movement of ordinary boundaries could be expected. This may account, therefore, for stationary grain boundaries<sup>1</sup> as well as the phenomenon of growth retardation through straining.<sup>10</sup> On the other hand, it is well known that grains in a deformed polycrystalline specimen have different degrees of straining, and this leads to the belief that many situations of unbalanced subboundaries could arise. It is suggested that strain-induced grain-boundary migration, reported by Beck and Sperry,<sup>12</sup> probably is this phenomenon.

**Subboundary Migration and Subgrain Coarsening:** Coarsening may be considered apart from any mechanism for release of subboundary energy. According to eq 4 the average energy per unit volume for a uniform substructure decreases logarithmically with  $\theta$ . This means that the available driving force for doubling the subgrain size is constant regardless of the initial size. If half the volume transforms to produce doubling, we have

$$\text{Driving force} = \frac{2E_s \ln 2}{R \cos \phi} \quad [5]$$

and this is somewhat less (a factor of 0.23) than the residual energy per unit volume for  $\theta$  equal to  $0.2^\circ$ .

Fig. 14—Enlarged Laue spot of specimen P4. a (upper)—As-bent. b (lower)—After 10 min at  $950^\circ\text{C}$ .

Theoretically two thirds of the volume could transform with  $\theta$  increasing to  $3\theta$  due to the coalescence of three boundaries with a

$$\text{Driving force} = \frac{3E_s \ln 3}{2R \cos \phi} \quad [6]$$

and this is about 0.27 times the  $0.2^\circ$ —residual. The coalescence of three subboundaries to form one, therefore, provides slightly more driving force than the coalescence of two, but the driving force is of course not large for either case.

The probability of one lamella growing at the expense of others as in exaggerated grain growth, for example, should be low in spite of an even more favorable driving force. At the start any one lamella is not favored to grow because the driving force is

$$\frac{2E_s \ln 2}{R \cos \phi} \text{ for each. After one lamella has doubled,}$$

however, the driving energy for its further growth is greater, because coalescence of a  $2\theta$ -boundary and a  $\theta$ -boundary releases more energy for the same volume change than the coalescence of two  $\theta$ -boundaries. The situation then improves with growth but not in a rapid manner; consequently other lamellae probably would grow also before one could become particularly large.

It must be remarked here that growth of a new

Fig. 15—Micrograph showing boundary and subboundaries of two grains A and B, with grain B in a complex polygonized state, after 4 hr at  $1300^\circ\text{C}$ .

Electro etch. X150. Reduced approximately 33 pct for reproduction.

grain at the expense of a polygonized grain (treated previously) does not have a constant driving force if growth alters the type of boundary enough to increase or decrease its specific energy.

If the driving energy is roughly constant for each stage of doubling as the above analysis would indicate, it is not at all clear why the coarsening should slow down at high temperatures. However, there must be a mechanism for the release of energy. We believe it is one of subboundary interaction quite analogous to that for ordinary grain growth. With increased annealing the reduction in number of interaction points such as that at P in Fig. 9d seems significant; interactions could move such points to the surface and thus coarsen the structure. When all have been used, coarsening should stop. On the other hand if sidewise movement of the subboundaries should occur because of unusual mobility (this is not a mechanism), some subboundaries occasionally would disappear during coarsening. Others should define very narrow lamellae just prior to disappearance, but the microstructures gave no strong evidence of this kind.

When parallel subboundaries are very close together, as they may be during polygonization, a force of attraction may exist between them, which would tend to make them coalesce. According to eq 2 if two like boundaries coalesce with one lamella going to zero width, the energy for the final subboundary will be less than that of the sum of the two initial subboundaries; so coalescence will reduce

Fig. 16—Laue photograph of boundary position in a two-grain specimen.

a (left)—As-prepared. Lattice of one grain strain free, lattice of other strained to  $21/32$  in. radius bend. b (right)—After additional bending and a 3-hr anneal at  $1300^\circ\text{C}$ .

the energy. Now if it is assumed that the change in energy occurs continuously, it follows that the force of attraction is the rate of energy variation with distance of separation. Somewhat larger forces of attraction reasonably could occur for polygonized cold-rolled crystals because adjacent boundaries could consist of dislocations of opposite signs whereas boundary dislocations in a bent sample are only of one kind.

The observed coarsening of subgrains in cold-rolled crystals may be likened to normal grain growth, except for the addition of a selective growth feature. Selective growth with removal of the orientation spread, of course, leads to a lower final energy state (because energy increases with difference in orientation) and should be favored therefore on a probability basis. On the other hand the selective growth may also involve subgrain sizes, smaller subgrains having orientations farthest from the average.

Although the removal of subboundary interaction points seems to account for the slowing down of coarsening in polygonized samples at high temperatures, the amount of movement of subboundaries at low temperatures, note Figs. 10a and 10b, suggest that some feature of the kinetics besides simple interaction and energy per unit volume may be involved. In a simple polygonization process the first lamellae formed have much smaller differences in orientation than those formed later as a result of coarsening. It would appear that a small difference in orientation favors subboundary movements. Generally, however, grain-boundary migration is favored by an appreciable difference in orientation. These somewhat contradictory facts can be reconciled if it is assumed that ease of boundary migration decreases at first with difference in orientation  $\theta$ , reaches a minimum value for a relatively small value of  $\theta$  (possibly about one degree) and then increases again.<sup>†</sup> According to dislocation theory, mobility should be high for very small values of orientation difference, but theory apparently has not advanced far enough to completely explain the role of orientation relationships. For that matter much remains to be done experimentally on the same problem.

### Summary

Single crystals of silicon iron were plastically deformed either by cold-rolling or by bending and were subsequently annealed. Results of a micrographic and X-ray investigation disclosed the following:

1. The phenomenon of removal of asterisms in Laue spots of cold-rolled single crystals without recrystallization results from two processes: (a) Polygonization, which produces a relatively fine subgrain structure and (b) subgrain growth of a fairly uniform kind like normal grain growth but selective in nature, removing the major spread in orientation and thereby producing a more nearly perfect single crystal of low subboundary energy.

2. Polygonization occurs in bent single crystals with subboundaries 90° to the active slip plane. As first formed the subboundaries are far from continuous and straight. With continued annealing irregularities disappear concurrently with coarsening of the lamellar substructure, which in one instance went as far as a ten-fold increase in lamellar

width. Theoretical considerations of the kinetics involved indicate a relatively small driving energy for coarsening.

Two-grain specimens were prepared in which either one or both of the grains contained subgrains. Annealing at high temperatures disclosed the following:

1. When one grain alone contains subboundaries, the other grain grows quite readily, apparently through interaction of the subboundaries with the ordinary boundary.

2. When both grains contain subboundaries, the ordinary boundary sometimes fails to move, apparently from lack of driving energy. At the same time, however, the subgrains grow larger. At other times the boundary does move, but in general the area swept is not free of subboundaries. Subboundaries are "pulled along," so to speak, since the ordinary boundary actually separates two sets of subgrains instead of two perfect crystal lattices. The available driving energy for the movement is the difference in subboundary energy per unit volume.

# Interface and Marker Movements in Diffusion In Solid Solutions of Metals

by Luiz C. Correa da Silva and Robert F. Mehl

An experimental study of the movement of markers in the systems Cu/ $\alpha$ -brass, Cu/Sn $\alpha$ -solid solution, Cu/Al $\alpha$ -solid solution, Cu/Ni, Cu/Au, Ag/Au, employing many types of markers and a variety of temperatures. Marker movement is confirmed and undoubtedly associated with the manner in which atoms move during diffusion.

SEVERAL years ago Smigelskas and Kirkendall<sup>1</sup> reported measurements on the interdiffusion of copper and  $\alpha$ -brass and on the movement of inert markers placed at the original join. These markers were observed to move toward the  $\alpha$ -brass side of the join, and from this it was inferred that zinc diffuses in  $\alpha$ -brass more rapidly than copper. Similar results were reported a little earlier for the diffusion of solvents into high polymer solids.<sup>2</sup> This has attracted much attention, particularly from those interested in the mechanism and the theory of diffusion: Seitz<sup>3</sup> has employed it in supporting the vacancy theory of diffusion; from the data Darken<sup>4</sup> has calculated separate diffusion coefficients for copper and zinc, developing a "phenomenological" theory of diffusion; and Bardeen<sup>5</sup> has employed it in constructing a general theory, including therein the work of Seitz and Darken, as has Le Claire.<sup>6</sup> These matters have recently been reconsidered in a symposium.<sup>7</sup>

Some reason has existed for questioning the work of Smigelskas and Kirkendall.<sup>1</sup> Their technique consisted in electroplating copper on  $\alpha$ -brass, upon the surface of which Mo-wires had been secured,

and then diffusing, measuring the extent of diffusion along the normal to the join, and measuring the marker displacement in the same direction by a comparator determination of the distance between Mo-wires on opposite sides of the electroplated brass sample. It has been suspected that the copper plate might have been porous, and that the original interface might have been an imperfect join, both contributing to the transfer of the volatile zinc by vapor transfer;<sup>8</sup> it has also been questioned whether the marker movement might not in a measure be a property of the marker itself; etc. These legitimate questions require experimental answers; the present paper offers such answers.

Moreover, Smigelskas and Kirkendall studied the effect only in the Cu-Zn system and at one temperature; the attention which the work of Smigelskas and Kirkendall has commanded recommends similar

| 93/7Al  | 92.65 | 0.002 | 0.030 | <0.005 |       | Rem.   | <0.002 | 0.002 | <0.01 |

OFHC copper and zinc of 99.99 pct Zn; it was melted in a graphite crucible under borax in an induction furnace. The 20 pct Zn alloy was cold-rolled 50 pct and annealed; this alloy appears in the couple C-17 (Table I). The copper was in the form of cylinders 3 in. in diam; the nickel was high-purity Mond nickel, received as disks 1 in. in diam and  $\frac{1}{4}$  in. thick.

Disks were cut to a diameter of  $1\frac{1}{4}$  in. (except in the case of Ni, left at 1 in.) and to thicknesses of  $\frac{1}{4}$  in. (for the Cu/Ni couples) or  $\frac{1}{2}$  in. (for all others). For the purposes of the experiments, the opposite faces had to be as nearly parallel as possible; with care this was done to  $\pm 0.0005$  cm; after machining the disks were polished carefully, usually with a finish from 4/0 emery paper. The surfaces were cleaned, degreased, and lightly etched with  $\text{HNO}_3$ .

The interface join markers employed were, variously:

- Type a. Molybdenum wire, 0.0075 cm diam.
- Type b. Tungsten wire, 0.0050 cm diam.
- Type c. Tungsten wire, 0.0010 cm diam.
- Type d. Platinum wire, 0.0075 cm diam.
- Type e. Platinum wire, 0.0025 cm diam.
- Type f. Platinum wire, silver coated, 0.0005 cm diam.
- Type g. Nickel wire, 0.0075 cm diam.
- Type h. Iron foil, 0.0025 cm thickness.
- Type i. Tantalum foil, 0.0025 cm thickness.
- Type j. Platinum foil, 0.0050 cm thickness.
- Type k. Nickel foil, 0.0075 cm thickness.
- Type l. Carbonaceous "wire"—made by carbonizing silk thread in vacuum.
- Type m.  $\text{Al}_2\text{O}_3$  powder (of polishing grade).
- Type n. Iron oxide "wire"—made by oxidizing a fine iron wire.

### Welding

The pressure applied for welding was the minimum possible for successful welding, usually in the neighborhood of 100 lb. The welding time was usually about 1 hr.

The specimens used usually consisted of three disks, the two outer disks identical, assembled as shown in Fig. 1. The markers in wire form were wound around the middle disk, as shown; this figure also shows the placing of foils. The composite of three disks were initially compressed hydraulically to 5000 to 15,000 lb to set the markers; this prepressing made subsequent welding much easier. After placing the disk composite in the furnace, the furnace was evacuated, then filled with hydrogen, the operation repeated several times at room temperature, and finally repeated several times while heating the furnace to  $600^\circ\text{C}$ ; the latter operation was omitted in the case of the brasses, owing to the risk of dezincing. In the case of the Cu-Al samples, special care was taken to remove all traces of oxygen (since hydrogen will not reduce  $\text{Al}_2\text{O}_3$ )—some Mg dust was employed as a getter. The time of welding was 1 hr or longer.

The metal disks were welded in the furnace sketched in Fig. 2. Heating was provided by resist-

Fig. 2—  
Welding  
apparatus.

studies on other systems over a range of temperatures; the present paper offers similar studies upon six alloy systems. Diffusion couples in the following systems have been studied: (1) Cu/ $\alpha$ -brass, 30 pct Zn and 20 pct Zn; (2) Cu/Cu-Al,  $\alpha$ -solid solution, 7 pct Al; (3) Cu/Cu-Sn,  $\alpha$ -solid solution, 10 pct Sn; (4) Cu/Ni; (5) Cu/Au; (6) Ag/Au. The diffusion couples were welded disks, and of the 29 couples all were double couples ("sandwiches"), e.g., Cu/Ni/Cu, except two. Table I lists the couples employed; it also gives times and temperatures of diffusion and the protective atmosphere employed.

### Materials

Most of the alloys were prepared through the courtesy of D. K. Crampton, of the Chase Brass and Copper Co. The analyses are listed in Table II. The 30 pct Zn alloy was received in the form of rolled slab, 1 in. thick; the Cu-Sn alloy was a forged flat bar  $\frac{1}{2}$  in. thick; and the Cu-Al alloy was a forged round bar  $1\frac{1}{2}$  in. in diam. In addition to the 30 pct Zn  $\alpha$ -brass supplied, one other brass was made of nominal composition 20 pct Zn; this was made from

Fig. 3—Imperfect weld showing wire markers and imperfectly welded join. X100. Reduced approximately 33 pct for reproduction.

ance elements; mechanical pressure was applied to the disks, through steel rods as shown; vacuum or controlled pressures of any desired gas was maintained through pump and manometer control. The heating element was Kanthal; rapid heating was possible—the disks could be brought to a welding temperature in 20 min; the temperature was kept constant during welding by a Celec tray control. Other details in the welding operation are obvious from Fig. 2. The thermocouple registered nominal temperatures only; these were high, approximating the melting point of the low-melting alloy; but the disks, held between steel plates, were actually at a substantially lower temperature; the thermocouple served only as a guide to reproduce the welding operation; the actual temperatures of the disks were not measured.

After welding, the specimens were machined with very great care, using a very sharp tool, the last layers removed were never thicker than 0.008 in., in order to minimize distortion, to produce two opposite planes accurately perpendicular to the welding zone and the marker; in the case of foil markers, four such surfaces were produced, related by right angles. This machining served two purposes: to reveal faulty welds on microscopic examination (whence many faulty specimens were discarded) and to provide an opportunity to establish the initial marker position. In the case of Cu-Zn alloys, this machining was deep enough to remove completely any dezincified outer layer. Fig. 3 shows the position of the wire marker with respect to the weld join (in an imperfect weld); other figures herein illustrate the weld zone in properly welded specimens. The inter-marker distance was determined with a comparator capable of yielding measurements reproducible within 0.0004 cm. Microscopic inspection showed the markers to be effectively equally imbedded in the opposing disks; the line of weld could be readily recognized.

#### Diffusion Treatments

The welded disk composites, when including brass, were annealed for diffusion in a steel container packed with brass chips (of the same composition as that in the disk composite) and lampblack (to prevent sticking of the charge), in order to avoid de-

Fig. 4 (upper left)—Sample C1 with foil marker after diffusion, unetched. X25.

Fig. 5 (upper right)—Sample E1 with foil marker after diffusion, etched. X25.

Fig. 6 (lower right)—Sample C3 with foil marker after diffusion showing final straightening of foil after prolonged diffusion.

zincing. As a result the Cu disks in all such composites were uniformly coated with a layer of brass, and the whole sample thus presented to the ambient a surface of the same composition, that of the high-Zn disk. For other disk composites hydrogen was used in general; Cu-Al alloys heated in hydrogen were observed to swell, perhaps because of hydrogen reduction of included oxides, and for this system nitrogen was used as a protective atmosphere. Cu-Al and Cu-Ni alloys were annealed in vacuum. Diffusion temperatures were maintained to  $\pm 2^\circ\text{C}$ .

#### Measurements on Diffused Couples

After diffusion, the flat longitudinal planes were re-machined, with similar care, in the case of Cu-Zn alloys this machining sufficed to remove completely

Table III. Displacement of Interface Markers

| Specimen            | Type of Markers at Each Interface                                                                                                                                                                                                                        | Temp, °C | Time of Diffusion, hr             | Shift at Each Interface, cm                              | Method of Measurement                                       | Observations                                                                                                            |

the outer layer which had absorbed Zn. The surfaces then were polished and etched; samples revealing faulty welds were discarded. The markers (and sometimes the original join) were visible on the final surface.

The diffusion-penetration curves (herein designated as *c-x* curves whatever units were used to express concentration and distance) were obtained from samples procured by machining. Machining was a critical operation; accurate specimen alignment with the lathe axis was obtained by the use of a mounted telescope with reticule, sighting upon the readily visible markers, rotating the specimen and adjusting; in some cases the weld line on an etched sample served equally well. Successive layers were machined normal to the lathe axis (parallel to the markers and join); the thickness of layers varied with the extent of diffusion; with small amounts of diffusion, and with nearly symmetrical diffusion-penetration curves, it was 0.0050 cm, or 0.0075 cm; in others, these same thicknesses were taken when the *c-x* curve varied sharply with distance, but when it varied but slowly thicker layers, 0.0150 and 0.0200 cm, were taken. The machined layers were analyzed chemically; in the Cu-Zn system usually Cu only was determined by chemical analysis, though both Cu and Zn were determined in sample

B20-II. Some 20 machined samples were analyzed for each *c-x* curve.\*

#### Measurement of Marker Position and Marker Shift

**Direct Method:** The initial distances between markers in double couples (sandwiches) were established after welding as noted above; after diffusion these distances were determined again in the same way; this is effectively the method employed by Smigelskas and Kirkendall<sup>1</sup>; it is denoted herein as the "direct method"; as in Figs. 47 to 55 and Table III these were reproducible to  $\pm 0.0004$  cm; since the markers were pressed between the metal disks before welding, the wires were imbedded in both disks (in Smigelskas and Kirkendall's electroplating technique the wires were not centered exactly at the join, but lay just off the join, imbedded in the electroplate); it was easy to locate the wires with respect to the welded join, and to observe the penetration of the disks by the markers, Fig. 3; in the Cu/ $\alpha$ -brass couples, the wires penetrated the Cu a little more than the  $\alpha$ -brass. Microscopic inspection showed that inclusions at the join move as do the markers; they thus also serve as markers. The

\* For the data from which *c-x* curves were plotted order Document 3115 from American Documentation Institute, 1719 N St., N.W., Washington 6, D. C., remitting \$1.00 for microfilm (images 1 in. high on standard 35 mm motion picture film) or \$1.05 for photocopies (6x8 in.) readable without optical aid.

Fig. 7 (left)—Showing placement of foil markers for measurement of changes in lateral dimensions.

direct method is not the best (as the data will show), for it probably suffers from secondary effects of creep, internal gas reactions, and possibly, though not certainly, dimensional changes resulting from internal stresses and recrystallization.

*Diffusion Curve Method:* The procedure of machining layers to determine the  $c$ - $x$  curve served to place the markers upon the  $c$ - $x$  curve, for when the markers were encountered during machining they could be recognized readily and thus associated with the composition of the layer machined at that point. The accuracy of the placement of the markers by this method was thus that of the thickness of the machined layer. As shown elsewhere, the position of the Matano interface was found to agree with the position of the original join, when lattice space is

Table IV. Matano Areas Observed in the Specimens Studied

| Specimen  | Time, hr | Temp, °C | Matano Area<br>(cm) (A/o) |
|-----------|----------|----------|---------------------------|

| B 23-I    | 224      | 804      | 0.10                      |
| B 33-I    | 524      | 808      | 0.16                      |
| B 46-I    | 504      | 733      | 0.07                      |
| B 38      | 362      | 947      | 0.51                      |
| C 4-I     | 312      | 1054     | 0.96                      |

employed; thus the difference in position of the marker and the Matano interface is the shift; this method is denoted herein as the “diffusion curve method,” see Figs. 47 to 55 and Table III. A single couple will suffice for this method.

*Foil Reference Method:* Impermeable foils inserted in the original join served as reference points for other, mobile markers; as noted elsewhere, this is a good method, for if the movement of the mobile markers is corrected for the (slight) movement of the centers of the "static" foils, then secondary effects of creep, etc., are excluded. In Figs. 47 to 55 and Table III, this is denoted as the "relative to foil" method.

Fig. 8—Probability plot of C-X curve for sample B20-1.

*Foil Bend Method:* This method is based upon the new observation that the edge of a foil placed at the join will bend progressively as diffusion occurs around it, Figs. 4 and 5. The middle portion of the "impermeable" foil will stay fixed as long as it is not affected by the diffusion occurring around the edges.

This also appears to give a reliable experimental method for obtaining the shift of markers caused by diffusion, since the movement of the foil tip can be measured (with respect to the unaffected middle portion) and such a measurement will not be affected by secondary volume changes occurring in the disks themselves. This method is denoted as the "foil bend method" in Figs. 47 to 55 and Table III. Interestingly enough, on very extensive diffusion, when diffusion had extended thoroughly around the foil, the foil "unbent," becoming flat again, Fig. 6.

### Measurement of Shift in Lateral Dimensions

All treatments of the work of Smigelskas and Kirkendall (and of other work) assume that there is no change in lateral dimensions, i.e., perpendicular to the direction of the diffusion current, though there have been no measurements of this. This measurement was made on a multiple sandwich, sample C19, with foils placed parallel to the diffusion direction, as sketched in Fig. 7. Three blocks of 30 pct Zn brass were welded with two iron foils placed as shown; this specimen then was machined to produce a plane surface perpendicular to the foil markers and then welded to a copper disk. Movement of these markers, spaced at a distance of 1.05 cm with respect to one another, served to evaluate

Fig. 10—Plot of three C-x curve for Cu/ $\alpha$ -brass couples for different values of time, abscissas  $x t^{1/2}$ .

Fig. 11 (left)—Log  $Mt^{1/2}$  vs.  $1/T$ , Cu/ $\alpha$ -brass couples.

Fig. 12 (right)—Graphical determination of maximum possible marker shift.

serves to “normalize” the curve—it is much easier to draw a “best fit,” to eliminate clearly spurious points. The curve drawn can then be used to re-draw the conventional curve (Fig. 9), and to calculate  $D = f(c)$ ; this is the method adopted in all cases.

Diffusion in solids occurs in a lattice; atomically, it appears that the process must consist of atom jumps from one lattice point to another, the distance of closest approach of atoms; it is unlikely that this elementary process should involve a multiple of this distance. Whatever the distance, movement must occur in steps in lattice space, which may be taken as the side of the unit cell,  $\bar{a}_0$  (or the distance of closest approach). Cartesian space is thus indirect in the process; advantages should accrue to plotting lattice space (or distance) instead of Cartesian space (or distance) and this method has been adopted. Such a plot obviously avoids the necessity for any correction of distance measured at room temperature to distance at the temperature of diffusion; on this basis a comparison of  $D$  at one concentration with  $D$  at another should be more fundamental. In studying marker displacement, this method has a special advantage: marker displacements originating in density changes are eliminated. The transformation from distance in terms of centimeters to distance in terms of the number of lattice ( $\bar{a}_0$ ) spacings, can readily be accomplished graphically; Fig. 9 is drawn on this basis. Diffusion coefficients calculated from such curves will have the dimensions  $(\bar{a}_0)^2$  per sec. The ordinate should be the number of atoms in the unit cell, although, since atomic percentage is linearly related to this in substitutional solid solutions, atomic percentage may be used. This method of plotting has been used wherever the precision of the data seemed to warrant the labor.

Since the present work is primarily a general experimental exploration of marker shift, only a few measurements were made on the rate of marker movement at one temperature (known from Smigelskas and Kirkendall<sup>1</sup> and Darken<sup>4</sup> to be parabolic);

lateral dimensional change. Measurements were made between the foils very near the interface and at a point well beyond the diffusion zone; some movement might be expected in the latter because of creep, etc.; the lateral shift is taken as the difference between the movements of the foils at the interface and those beyond the diffusion zone. The diffusion temperature was 884°C and the time 73 hr. Diffusion-penetration curves were not made, but can be calculated from the other data for this system.

### Methods of Plotting Results

The  $c$ - $x$  curves are plotted conventionally as concentration, either in weight or atomic percentage, vs. distance in usual units. As is well known (see, for example, ref. 9), if the diffusion coefficient  $D$  does not vary with the concentration, this plots as a straight line on probability paper; if  $D$  varies with concentration ( $D = f(c)$ ) the curve is bent, as in all cases herein. Such a plot, however (Fig. 8),

Table VI. Marker Shifts and Matano Areas

| Specimen            | Matano Area (cm) (A/o) | Shift of markers (cm) | Observations     |
|---------------------|------------------------|-----------------------|------------------|
| <b>Cu-Zn System</b> |                        |                       |                  |
| B 20                | 0.98                   | 0.0109                | From diff. curve |
| B 35                | 0.96                   | 0.0084                | From diff. curve |
| B 36                | 1.34                   | 0.0190                | From diff. curve |
| B 37                | 1.29                   | 0.0148                | From diff. curve |
| B 42                | 0.42                   | 0.0048                | Rel. to foils    |
|                     | 0.85                   | 0.0094                | Foil bending     |
| B 45                | 0.40                   | 0.0047                | Rel. to foils    |
|                     | 0.84                   | 0.0105                | Rel. to foils    |
|                     | 0.84                   | 0.0089                | Foil bending     |
| C 1                 | 0.40                   | 0.0035                | Rel. Ta foil     |
| E 1                 | 0.62                   | 0.0052                | Rel. to foils    |
|                     | 0.62                   | 0.0079                | Foil bending     |
| <b>Cu-Al System</b> |                        |                       |                  |
| B 34                | 0.72                   | 0.0014                | Total shift      |
|                     | 1.11                   | 0.0021                | Total shift      |
|                     | 1.48                   | 0.0023                | Total shift      |
| B 39                | 0.60                   | 0.0011                | Total shift      |
| C 6                 | 1.21                   | 0.0026                | Total shift      |
| <b>Cu-Sn System</b> |                        |                       |                  |
| B 23                | 0.102                  | 0.0030                | Total shift      |
| B 28                | 0.094                  | 0.0028                | Total shift      |
| B 41                | 0.046                  | 0.0012                | Rel. to foils    |
|                     | 0.087                  | 0.0024                | Rel. to foils    |
| B 46                | 0.072                  | 0.0023                | Total shift      |
| <b>Cu-Ni System</b> |                        |                       |                  |
| B 38                | 0.51                   | 0.0039                | From diff. curve |
| C 4                 | 0.96                   | 0.0140                | From diff. curve |
|                     |                        | 0.0094                | Direct measure   |
| <b>Ag-Au System</b> |                        |                       |                  |
| D 2                 | 3.4K                   | 0.0113                | Direct measure   |
| D 3                 | 2.7K                   | 0.0113                | Direct measure   |

a variety of temperatures and times was used. It would be useful to have a method to compare the results obtained. An approximate method has been derived and will be employed in treating some of the data.

The penetration  $x$ , for a given concentration, ( $c$ ), depends upon time, as is well known, by the relation:

$$x(c) = k(c) \cdot t^{1/2}$$

Since all points in a diffusion curve obey this relation, it is obvious that, from a single diffusion curve for a given time, the diffusion curve corresponding to any other time (at the same temperature) may be derived. The inverse, of course, is also true: we can reduce all diffusion curves (for different times, at a given temperature) to a single master curve, if instead of distance  $x$  we plot  $(x \cdot t^{-1/2})$ , Fig. 10 (plotted from the data of Rhines and Mehl<sup>10</sup>).

If we wish to compare diffusion curves (or shifts) obtained at different temperatures, the following approximate treatment may be used:

The usual expression for  $D$ :

Fig. 18—C-X curve and marker position for sample B34-I, Cu/αCu-Al.

Fig. 19—C-X curve and marker position for sample B39-I, Cu/αCu-Al.

Fig. 20—C-X curve and marker position for sample B23, Cu/αCu-Sn.

$$D = A \cdot e^{-Q/RT}$$

can be written:

$$D(c,T) = A(c) \cdot e^{-\frac{Q(c)}{RT}} \quad [1]$$

indicating that, for a given solid solution,  $D$ ,  $A$ , and  $Q$  depend on the concentration. If we are dealing with relatively small temperature intervals, or if we are satisfied with only an approximate treatment, we may substitute an average, constant value  $Q_{av}$  for the function  $Q(c)$ :

$$D(c,T) = A(c) \cdot e^{-\frac{Q_{av}}{RT}} \quad [2]$$

Consequently, if we know the function  $D(c,T)$  for a temperature  $T_1$ , its value at  $T_2$  is given by:

$$D_2(c) = e^{\frac{Q_{av}}{R} \cdot \frac{T_2 - T_1}{T_2 T_1}} \cdot D_1(c) \quad [3]$$

which is equivalent to the displacement of  $D = f(c)$  by a constant amount:

$$D_2(c) = K \cdot D_1(c) \quad [4]$$

In this treatment, then, passage from temperature  $T_1$  to  $T_2$  is equivalent to multiplying the coordinates  $x$  of the diffusion curve by a constant  $\sqrt{K}$ .

Thus, we may write, as an approximation (eq 3 above):

$$D_2(c) = e^{\frac{Q_{av}}{R} \cdot \frac{T_2 - T_1}{T_2 T_1}} \cdot D_1(c) \quad [3a]$$

and

$$x_2(c) = e^{\frac{Q_{av}}{2R} \cdot \frac{T_2 - T_1}{T_2 T_1}} \cdot x_1(c) \quad [5]$$

Fig. 25— $D = f(c)$  for samples B37-I, II, Cu/ $\alpha$ -brass.

Fig. 29— $D = f(c)$  for sample B35-II, Cu/ $\alpha$ -brass.

Fig. 26— $D = f(c)$  for sample B20-I, Cu/ $\alpha$ -brass.

Fig. 27— $D = f(c)$  for sample B36-II, Cu/ $\alpha$ -brass.

Fig. 28— $D = f(c)$  for sample B35-I, Cu/ $\alpha$ -brass.

If the time also varies, then:

$$x_2(c) = \sqrt{\frac{t_2}{t_1}} \cdot e^{\frac{Q_{av}}{2R} \cdot \frac{T_2 - T_1}{T_2 T_1}} \cdot x_1(c) \quad [6]$$

or, in general:

$$x(c) = K(c) \cdot t^{1/2} \cdot e^{-\frac{Q_{av}}{2RT}} \quad [7]$$

This is approximate, but it predicts the actual shape of the diffusion curve quite well, knowing the diffusion curve for a given  $t$  and a given  $T$ .

The Boltzmann-Matano area (hereinafter the "Matano area") is that on either side of the Boltzmann-Matano interface (the "Matano interface"). These areas, as measured from the diffusion curves, are given in Table IV. This area measures the amount of diffusion; if atoms are conserved on lattice points, it represents the number of atoms diffused. It varies linearly with  $x$  and  $t^{1/2}$  and can be written:

$$M = K_M \cdot t^{1/2} \cdot e^{-\frac{Q_M}{2RT}} \quad [8]$$

Again  $Q$  is averaged over a concentration range. This area is less subject to error since slopes and small areas are not measured, as they are in calculating  $D$ .

The values of  $K_M$  and  $Q_M$  in eq 8 may be obtained from a plot of  $\log_{10}(M/t^{1/2})$  vs.  $1/T$ , employing the data from Table IV; Fig. 10 gives the plot for the system Cu-Zn (similar plots were made for the other systems); the plots serve to show that eq 8 is satisfactory; the derived values for  $K_M$  and  $Q_M$  are given in Table V. Using eq 8 and the data in Table V, the Matano areas have been calculated for those specimens in which marker displacements have been measured; these marker displacements and corresponding Matano areas are given in Table VI. These are the data used in Figs. 11 to 15; since the marker shift varies with  $t^{1/2}$ , it should also vary linearly with the Matano area.

In the Ag-Au system values of  $K_M$  and  $Q_M$  were not available, the comparison of the two measured shifts was approximated by assuming a  $Q$ -value of 26,600 cal per mol.<sup>11</sup> This value may be too low.

### Maximum Possible Shift

If it is assumed, as others have, that the marker shift results from unequal countercurrent diffusion flow, it is possible to calculate, in some of the present cases, the marker displacement that would result if the diffusion coefficient of one of the atomic species were zero—if one of the atomic species did not cross the marker at all. This shift will be desig-

Fig. 30— $D = f(c)$  for sample B22-I,  
Cu/ $\alpha$ Cu-Al.

Fig. 31— $D = f(c)$  for sample B34-I,  
Cu/ $\alpha$ Cu-Al.

nated as the "maximum possible shift,"  $S_{\max}$ . Such a calculation assumes that no measurable voids are created, and that all dimensional changes are in the direction of diffusion flow.

Fig. 12 represents a diffusion curve in lattice units, for diffusion between a metal and its terminal solid solution. Areas in this diagram are proportional to numbers of atoms. At the outset, the number of B atoms is proportional to the area MHPN. If B atoms cross the markers toward the left without any A atoms crossing toward the right, the markers will move to a new position WL in such a way that the area EFM and FKLK will be equal. The maximum possible shift would then be the shift from MK to WL. The values of  $S_{\max}$  in terms of lattice units are then reconverted to cm, and plotted against cm, as in Figs. 48 to 53.

### c-x Curves

The data are plotted in Figs. 9 and 13 to 24; the abscissas are lattice spacings where possible. As noted, Fig. 13 plots data for both couples in a sandwich; the correspondence speaks well for the reproducibility of such data.

$$D = f(c)$$

From the above curves, the variation of  $D$  with concentration can be plotted ( $D = f(c)$ ); the results are plotted in Figs. 25 to 36. Fig. 37 is a comparison of the  $D = f(c)$  curve for the Cu/20 pct Zn couple, as determined at 923°C as compared with a similar curve for the couple Cu/30 pct Zn, extrapolated from the curves for this couple obtained at lower temperatures. In the Cu/20 pct Zn couple, the  $D$ -values above about 10 pct Zn are for compositions losing Zn during diffusion, below 10 pct Zn for compositions gaining Zn. In the Cu/30 pct Zn couple the dividing composition is about 15 pct. The curves suggest that for a given composition, the  $D$ -value is the higher when that composition is losing Zn than when gaining, as though the act of losing Zn creates a structural degeneracy which favors a higher mobility. Fig. 38 is a recalculation of the earlier data of Rhines and Mehl,<sup>10</sup> for somewhat similar couples. The results are essentially the same. This result is highly tentative, for the comparison for the Cu/20 pct Zn couple is necessarily made for the high-Zn side, i.e., near one end of the diffusion-penetration curve where the accuracy is not good. The curves for the Cu/30 pct Zn couple, comparing the present results with the earlier ones

Fig. 32— $D = f(c)$  for sample B39-I.

Fig. 33— $D = f(c)$  for samples B23 and B33, Cu/ $\alpha$ Cu-Sn.

Fig. 34— $D = f(c)$  for sample B46, Cu/ $\alpha$ Cu-Sn.

of Rhines and Mehl show remarkably good agreement.

### Activation Plots

From the preceding data, eq 1 may be plotted for the systems Cu-Zn, Cu-Al, Cu-Sn, and Cu-Ni, Figs. 39 to 42. The activation plot for Cu-Ni, Fig. 42, and the plot of  $Q = f(c)$ , Fig. 45, are surprising; probably further study is needed. The activation plot for Cu-Zn, Fig. 39, shows wide scatter, possibly reflecting appreciable variation in measured  $D$ -values as a result of grain-size differences at low temperatures.<sup>17</sup>

$$Q = f(c)$$

The values of the activation energy  $Q$  as a function of concentration ( $Q = f(c)$ ) may now be plotted, Figs. 43, 44, 45, and 47. These values for the systems Cu-Zn, Cu-Al, and Cu-Sn are in fair agreement with those of Rhines and Mehl;<sup>10</sup> in all cases the direction of change of  $Q$  with increasing concentration is the same. The values of  $Q$  calculated by Rhines and Mehl were known to be highly approximate; these new values are probably better. Fig. 46 plots the frequency factor  $A$  as a function of concentration for the system Cu-Zn.

### Marker Displacement

The methods are given above. The measurements are listed in Table III. The results are plotted in Figs. 48 to 56; in several of these the ordinate is  $t^{1/2}$ , in others the Matano area.

Table III gives the types of markers, the temperature and the time of diffusion, the shift measured, and the method used. Note that several methods are occasionally included in one sample, such as B-45, E-1, etc. Moreover, in some cases markers of different materials were included in one sample, of which sample C-20 is an important example. In this case and in other cases, all markers, whatever their nature, moved by exactly the same amount; the amount of bending of foil markers, whatever their composition, was the same. These materials vary markedly in chemical nature and in physical form and dimension.

Inasmuch as some possibility obtained that marker movement might be related to transport of matter at the interface around an insoluble wire (and therefore be related to diffusion only most indirectly), wire markers were used which dissolved in the matrix; these were of Ni and Pt; Ni dissolved too rapidly; Pt, however, in wire form, 0.001 in. diam, was useful: though it dissolved, the point where it had been (and where the Pt concentration was still high) could be recognized clearly upon etching; this marker moved the same distance as all the others. As noted, the Matano areas, and corresponding marker shifts, are given in Table VI.

Fig. 48 gives the data for the Cu-Zn system at 882°C plotted against  $t^{1/2}$ . As remarked above, data from the direct method are probably most unreliable; these points are represented by open circles, triangles, etc.; the data from the presumably more trustworthy experiments, resulting from application of the other methods ("reference to foils," etc.),

Fig. 35 (top)— $D = f(c)$  for sample C4-I, Cu-Ni.

Fig. 36 (second from top)— $D = f(c)$  for sample B38, Cu-Ni.

Fig. 37 (third from top)— $D = f(c)$  for sample C17-I, Cu/α-brass.

Fig. 38 (bottom)—Comparison of diffusion data for 834° and 840°C, Cu/α-brass.

Fig. 39—Log D vs.  $1/T$ , Cu/ $\alpha$ -brass.

Fig. 40—Log D vs.  $1/T$ ,  
Cu/ $\alpha$ Cu-Al.

Fig. 41—Log D vs.  $1/T$ ,  
Cu/ $\alpha$ Cu-Sn.

are represented by filled-in points; the curves "observed shift" are drawn from these, ignoring the others. The great scatter shown in the points from the "direct method" is evidence that this method does not yield consistent data and is presumably somewhat unreliable. Using only the filled-in points, the parabolic law is reasonably obeyed. The shift is toward the high-Zn side of the couple (see Figs. 48 to 51) and is nearly the maximum possible shift. Fig. 49, representing data for 834°C, seems to show that the maximum possible shift is nearly attained, though the data are few.

Fig. 50 is a similar plot for a temperature of 784°C; again the shift is near to the maximum possible. The data of Smigelskas and Kirkendall are placed on this diagram; the agreement with the current data is fairly good. The points represented by upright triangles probably should be disregarded, for reasons noted above, and have been disregarded in drawing the curve of observed shift; all points from the direct method have been disregarded. These data include reversed couples, i.e., both Cu/30 pct Zn/Cu couples (as employed by Smigelskas and Kirkendall) and 30 pct Zn/Cu/30 pct Zn couples. No significant difference in the marker shift upon couple reversal is evident.

Fig. 51 combines the data, plotting the Matano area as abscissa. The parabolic law is evident; the current data (here as elsewhere) suggest that the shift is somewhat greater than that measured by Smigelskas and Kirkendall; it shows also that the shift is not far from the maximum possible.

Fig. 52 gives a similar plot for the Cu-Al system. The marker displacement is toward the high-Al side of the couple. It is but a fraction of the maximum possible shift.

The marker displacement in the Cu-Sn system, Fig. 53, is toward the high-Sn side of the couple. Most surprisingly, the shift is greater than the "maximum possible"; the data are few, however, and difficulties in chemical analysis (especially in

Fig. 43 (second from bottom)— $Q = f(c)$ , Cu/ $\alpha$ Cu-Sn.

Fig. 44 (bottom)— $Q = f(c)$ , Cu/ $\alpha$ Cu-Al.

Fig. 45— $Q = f(c)$ , Cu-Ni.

view of the small concentration range involved, viz., 5.5 atomic pct) may render them untrustworthy. The unexpected and even startling nature of these results recommend further study. The results on the systems Cu-Al and Cu-Sn probably suffer from inferior accuracy.

In the Cu-Ni system, the shift is toward the high-Cu side of the couple, Fig. 54. The data are too few to permit a detailed study.

Fig. 55 is an approximation (as noted elsewhere) for the shift in the Ag-Au system, as plotted against (an approximation of) the Matano area. The shift is toward the high-Ag side of the couple.

Fig. 56 is a plot of the shift for the system Cu-Au, plotted against  $t^{1/2}$ . The shift is toward the high-Au side of the couple.

#### Lateral Shift

The method used has been described above; the results are given in Table III, sample C-19. The lateral shift is 0.0007 cm; this is a value for the shift observed in the foils at the interface, corrected for a small shift observed at the other ends of the foils (caused, presumably, by creep, etc.). At the beginning of the diffusion treatment, the composition at the Cu/ $\alpha$ -brass interface was 30 atomic pct Zn; after diffusion this became 21 atomic pct; the lateral shift due to lattice parameter change at this point should be 0.0075 cm, and this should be a decrease in the inter-foil distance at the Cu/ $\alpha$ -brass interface. The observed shift is but one tenth of this. Moreover, if all dimensions of the brass were to decrease by the amount which the ordinary markers shift, i.e., if the shift of the ordinary markers reflects a simple decrease in volume of the brass,

Fig. 46— $A = f(c)$ , Cu/ $\alpha$ -brass.

then a further contraction of 0.0080 cm should occur. These special foil markers thus seem quite inert.

This single observation seems to indicate that dimensional changes are entirely unidirectional—in the direction of the diffusion stream. This validates the common theoretical assumption, though the oddity of the phenomenon would appear to demand further study.

#### Micrographic Studies

Figs. 56 to 58 illustrate the grain structure obtaining at the interface. Apart from deliberately inserted markers, which can readily be seen, some inclusions are visible (on unetched as well as on etched samples, though not easy to show in reproduction); as noted, these inclusions also constitute markers, and move as others do; the micrographs serve also to show the markers in relation to the join.

On the original welded samples, the weld join is, of course, a straight line forming a linear multigrain boundary. This multigrain boundary tends to persist with diffusion, frequently remaining quite straight though sometimes curved; thus grain growth occurs at this point, since the markers move and the grain boundary moves with the markers, during diffusion. It is possible that this is evidence for strain accompanying diffusion, with the generation of imperfections including those of the dislocation type. The long times and the high temperatures of diffusion cause general grain growth; observations of the couples after diffusion are given in Table VII. Much study remains to be done with

Fig. 47— $Q = f(c)$ , Cu/ $\alpha$ -brass.

respect to grain structure changes during diffusion, and it is more than possible that this will contribute much to the subject and even to the theory of diffusion.<sup>†</sup>

In couples in the Cu-Zn system, some porosity is evident. This porosity (to be distinguished from the very slight traces of "porosity" normally seen in polished sections of alloys, to be ascribed to the embedding of abrasive particles) occurs on the high-Zn side of the couple, Fig. 59. This is the "porosity" observed by Smigelskas and Kirkendall. It is evident, though barely so, in unetched specimens; etching presumably exaggerates it. It does not occur in the high-Cu side of the markers, nor in the immediate neighborhood of the markers, but a very little distance from it. The porosity appears abruptly and is greatest near the marker and decreases in amount with distance from the marker. It occurs only in the diffusion zone—it does not extend beyond it.

<sup>†</sup> These studies are under way, with special emphasis on the use of single crystals and the structural changes that occur in these.

Table VII. Grain Sizes Observed on Couples After Diffusion

| Specimen | Couple                  | Treatment       | Grain Size, mm              |
|----------|-------------------------|-----------------|-----------------------------|
| C-3      | Cu/70Cu-30Zn/Cu         | 267 hr at 883°C | $\alpha$ -brass:1-4; Cu:0.5 |
| C-11     | 70Cu-30 Zn/Cu/70Cu-30Zn | 85 hr at 882°C  | $\alpha$ -brass:2-4; Cu:1-4 |
| C-14     | Cu/70Cu-30Zn/Cu         | 112 hr at 884°C | $\alpha$ -brass:3-8; Cu:1-3 |

Very interestingly, the porosity is evident around the edge of a reference foil, Fig. 4. Despite some effort, this type of porosity was not found in general in the other systems studied, though some slight evidence for it was exhibited in the Cu-Al samples. It suggests, very tentatively, a degeneracy of the structure caused by diffusion.

### Hardness Studies

The suggestion that the observed porosity may be evidence of structural degeneracy led to a study of the Knoop microhardness, with 100 g loads (heavier loads did not show the effect) across the diffusion interface. Nine sets were made on the polished sample, normal to the join. Each set consisted in ten measurements, at intervals of 0.0125 cm. These nine sets were arranged so that the different results on different grain orientations would be averaged and this variable eliminated. The total range studied was 0.050 cm, corresponding to a concentration range of 18 to 24 atomic pct Zn. The results are given in Fig. 60. The microhardness of pure Cu was

Fig. 48—Data on marker shift,  $S = K_s t^{1/2}$ , Cu/ $\alpha$ -brass, 822°C.

found to be 95, and that of the 70-30 composition 120; under the conditions of measurement, these values are wholly relative, though proportional to the usual Knoop hardness values. It would be expected that the hardness would change continuously, but the results show a sudden drop on the high-Zn side; this sudden drop appears at about the point where "porosity" becomes evident, and the hardness remains anomalous in the zones of porosity. This is what might be expected in a porous or otherwise degenerate structure. The results previously noted on diffusion-penetration curves, Figs. 37 and 38, might lead to a similar conclusion: that degeneracy obtains in these parts of a couple that lose Zn. This is wholly tentative; further study is certainly required.

### Discussion

**Phenomenological:** The movement of inert markers in diffusion couples involving a single solid solution is real in the sense that it is a direct concomitant of the diffusion process only and is not an effect originating in nondiffusional processes. The

Fig. 49—Data on marker shift,  $S = K_s t^{1/2}$ , Cu/ $\alpha$ -brass, 834°C.

effect occurs whatever the nature of the marker, and the magnitude of the effect is identical with all markers, even in the case when the marker is not inert but dissolves. Neither the occurrence of the effect nor its magnitude is dependent upon the method of joining the couple (when metallic contact is intimate)—welding and electroplating give nearly the same result. Neither the effect nor its magnitude is dependent upon: (1) The outer geometry of the sample, for the result is the same for couples in which one side is a thin electroplate<sup>1</sup> as for couples in which both parts are heavy blocks, as in the present work; (2) couple reversal, for the marker displacement of a couple of the type A/B/A is identical with that for a reversed couple, B/A/B; (3) differences in the specific reactivities of the surfaces of the component metals with respect to the formation of vacancies, for the surfaces of both parts of the Cu/ $\alpha$ -brass couples were coated with a layer of  $\alpha$ -brass of uniform composition (see discussion below).

The effect occurs in lattice space, and methods are given by which the magnitude of the effect in lattice space may be shown. The effect seems to be unidirectional, occurring only in the direction of diffusion flow, judging from only one—though albeit quite careful—experiment which demonstrated no dimensional change perpendicular to the direction of diffusion flow.

The effect and its magnitude can be affected by secondary factors, such as creep, internal gas generation, and possible recrystallization, but these (except recrystallization) can be experimentally avoided and the basic effect confirmed and accurately measured by newly developed techniques;

Fig. 50—Data on marker shift,  $S = K_s t^{1/2}$ , Cu/ $\alpha$ -brass, 784°C.

Fig. 52—Data on marker shift, plotted against Matano area, Cu/αCu-Al.

spurious effects are especially pronounced at high temperatures—thus, in Cu/α-brass couples they are negligible at 785° and 834°C, but appreciable at 882°C; the direct method (used by Smigelskas and Kirkendall) gives results which agree with those obtained by better methods of measurement at the two lower temperatures, but not at the high temperature.

The original interface is unambiguously given by the original positions of the unbent portions of the foil markers; the number of atoms on either side is unchanged since there is no diffusion normal to the unbent portions. The bending of the foil edge, as measured from the unbent portion, is thus the shift with respect to the original interface. Inasmuch as all other markers move quantitatively identically with the bending of the foil edge, then all marker shift is referred to the original interface as defined by the unbent foil. Measurements show that the amount of movement is identical with the marker movement referred to the Matano interface. The Matano interface thus defines the original interface. Inasmuch as the whole diffusion area is computed in determining the Matano interface, atoms are conserved on lattice points (else volume increases caused by lattice degeneracy—voids, etc.—would have given a discrepancy between the Matano interface and the original interface). Accordingly, volume anomalies, such as voids (porosity) are too small to be detectable; no change in normal lattice

site vacancies would be expected to give a measurable volume anomaly, for appraisals of the probable fraction of vacant lattice sites show this effect to be beyond these measurements.

**Mechanism:** Smigelskas and Kirkendall proposed that the movement of markers may be taken as evidence that one component of the solid solution diffuses more rapidly than Cu and that the markers move with a bulk movement. All subsequent writers have adopted this point of view. Darken,<sup>4</sup> taking the marker as the origin of a frame of reference for diffusion flow and counterflow, provided a method of calculating the respective dual diffusion coefficients, finding  $D_{Zn} > D_{Cu}$ . Similar calculations can be made for the measurements on the several systems reported herein. (In passing, it should be noted that this in no way invalidates the Matano analysis; this remains a complete quantitative description of c-x diffusion curves.<sup>2</sup>)

Darken's presumption depends upon the somewhat difficult concept of the movement of the "body" of the lattice, which the markers accompany. The validity of this concept, however, appears undoubted in view of the present observation that dissolved Pt markers move as do inert, insoluble markers, for the high-Pt regions are patently integral with the lattice; the much lower magnitude of the diffusion coefficient of Pt renders these regions relatively immobile. (At 800°C the diffusion coefficient of Pt in Cu<sup>12</sup> is one to two hundredth of that of Zn in α-brass.<sup>10</sup>) Radioactive tracers, used recently in this laboratory as markers in the study of multiphase oxidation layers, would doubtless provide similar evidence.

Darken's treatment is purely "phenomenological," i.e., it provided a quantitative treatment of the phenomena but did not contrive a mechanism. Seitz<sup>8</sup> pointed out that diffusion by means of direct atom interchange cannot offer a basis for marker movement, though diffusion through the action of vacancies can, recalling<sup>13</sup> that calculations of diffusional activation energies from first principles for face-centered cubic substitutional solid solutions of a Cu prototype show a preference for diffusion by vacancies over diffusion through interstices, and show that simple two-atom interchange would require prohibitively high energies. Recent calculations by Zener,<sup>14</sup> while altering some numerical values, retain this order of preference; Zener showed on a basis of energetics that a four-atom ring interchange, though requiring more energy than vacancy interchange (though not much) in

Fig. 53—Data on marker shift, plotted against Matano area, Cu/αCu-Sn.

Fig. 54—Data on marker shift, plotted against Matano area, Cu-Ni.

Fig. 55—Data on marker shift, plotted against Matano area, Ag-Au.

face-centered cubic lattices, may be the preferred mechanism in body-centered cubic lattices. Presumably, then, marker movement would not occur in the latter type of lattice (a matter now under study in this laboratory). These calculations are based, to be sure, upon geometrically ideal lattices; whether in real lattices, characterized by subgrain structural units of various types, vacancy diffusion alone obtains, cannot be said. If there be a fine structure to diffusion processes (a possibility deserving attention), with rapid diffusion along the surfaces of imperfection, then a real diffusion process must be represented by a series of fundamental diffusion equations of type 1, each applying to a single structural type of diffusion, as Smekal early proposed,<sup>15</sup> and the atom movement process would be a combination of several types, and, indeed, atom movement mechanisms prohibited in perfect lattices might well occur in the disorder of imperfections.

Seitz,<sup>3</sup> accepting Smigelskas and Kirkendall's idea of mass flow and Darken's analysis, then proposed that the result  $D_{Zn} > D_{Cu}$  means fundamentally that the interchange Zn-vacancy is easier than the interchange Cu-vacancy, so that in the couple Cu/ $\alpha$ -brass vacancies stream predominantly from left to right and Zn atoms from right to left. The accumulation of vacancies to the right was thought to produce voids (manifesting porosity) which in time disappeared by a sintering process, thus providing mass flow; this requires a source of vacancies; he thought the electroplated Cu might be characteristically high in voids and hence vacancies, but conceived the abiding source to be the outer surface of the sample. On this basis, mass flow was held to occur over a

much greater volume than that of the diffusion zone; Darken held it to be restricted to the diffusion zone; Seitz stated that the issue would be resolved by couple reversal, saying that if  $\alpha$ -brass were on the outside of the couple and Cu inside the marker movement would be reversed also. The present work favors Darken on the latter point and greatly limits the possibilities as to the source of vacancies.

The proposal that the stimulating vacancy flow originates at the specimen surface appears quite unlikely: the present experiments show that the marker movement does not vary in any way with the geometry of the sample; couple reversal is without result; the thickness of the Cu portion of the couple is without effect, since nearly the same result was obtained in the present work, where thick Cu disks were used as in Smigelskas and Kirkendall's work, where a thin electroplate was employed. Vacancies in any event could hardly, in the present experiments, have originated in the surface, for the Cu/ $\alpha$ -brass couples were in fact completely covered with  $\alpha$ -brass of the same composition, presumably providing vacancies equally to both elements in the couple, yet the results were nearly the same as those of Smigelskas and Kirkendall where the couple exhibited the surface of only Cu to the ambient. If the porosity observed in the  $\alpha$ -brass portion of the Cu/ $\alpha$ -brass couples is intimately related to mass flow process, then, so far as this portion of the couple is concerned, the effect does not extend throughout the volume of the sample, but is restricted to the diffusion zone.

The vacancy mechanism requires that (1) vacancies be created in the Cu side of the Cu/ $\alpha$ -brass couple, and (2) that (after diffusing) they be destroyed on the  $\alpha$ -brass side. In the light of the present findings, these processes must be limited to the diffusion zone; and in view of the finding that the lateral dimension does not appreciably change, the creation of vacancies in Cu and their diffusion toward and destruction in the  $\alpha$ -brass must remove lattice planes perpendicular to the direction of diffusion in the  $\alpha$ -brass and add perpendicular planes in the Cu.<sup>‡</sup>

The migration of vacancies from the Cu to the  $\alpha$ -brass is not enough to explain mass flow, for it does not in itself explain how lattice planes are added on the Cu side and destroyed on the  $\alpha$ -brass side while maintaining lateral dimensions unchanged. Dislocations might here be advanced as a helpful aid: Fig. 61 illustrates the shrinkage of the  $\alpha$ -brass side of the couple in terms of a simple edge type of dislocation. On this side of the couple,

<sup>‡</sup> For simplicity in discussion the Cu/ $\alpha$ -brass couple will be used as a prototype, with what is said applying also to the other systems studied.

Fig. 58—Micrograph of sample B22, Cu/αCu-Al,  $K_2Cr_2O_7$  etchant, showing one wire. X100.

vacancies presumably could combine, forming a line of vacancies perpendicular to the direction of diffusion flow; this combination could then shrink to a dislocation of the type shown in Fig. 61 IV. This effectively destroys a lattice plane, giving marker movement as pictured, and maintains the constancy of lateral dimensions. Any three-dimensional void would provide three-dimensional contraction, and dislocations oriented otherwise than pictured would do likewise. Presumably it is the elastic restraint of the couple as a whole that restricts contraction to

the plane perpendicular to direction of diffusion flow.

Inasmuch as there is reason to believe that even annealed metals exhibit a characteristic concentration of dislocations, Zn atoms wandering toward the Cu, there find dislocations awaiting, and by a simple reversal of the process shown in Fig. 61, destroy a dislocation by occupying positions between dislocation edges, thus ultimately creating a new lattice plane.<sup>§</sup> This is a simple scheme offering possibilities of elaboration.\*\*

This mechanism meets the requirements: lattice planes are destroyed on the α-brass side and created on the Cu side. The interaction of vacancies and dislocations is fundamental. It is probably oversimple to think of the two processes of destruction and creation as restricted respectively to the extremes of the diffusion zone; they would probably overlap within that zone. The creation of voids or porosity is not necessary, and indeed voids are not found in some systems studied herein, as noted above; whether or not voids form probably relates to the ease with which dislocations may form.

The marker shift varies greatly from system to system. In the Cu-Zn, Cu-Al, Cu-Sn systems the markers moved away from the Cu side of the couple; in the Cu-Ni system, toward the Cu side; in the Ag-Au system, toward the Ag side; in the Cu-Au system, toward the Au side. The magnitude of the marker shift varies greatly: it is relatively great in the Cu-Zn, Cu-Ni, and Ag-Au systems, and relatively small in the Cu-Al and Cu-Sn systems. As Darken's analysis<sup>4</sup> shows, these movements can be referred to the respective values of two diffusion coefficients for each system. And in turn this implies a greater rate of interchange with vacancies

<sup>§</sup> In those systems in which there is a marked change in lattice dimensions with concentration, stresses may well arise causing plastic flow and resultant recrystallization and grain growth, multiplying the dislocation concentration and facilitating the process pictured; there is ample evidence that recrystallization, or at least grain boundary movement, does occur in diffusion in α-brass.<sup>17</sup>

\*\* Having seen this proposal, Seitz<sup>18</sup> has further developed it, employing dislocations of the ring type.

of the atom with the greater separate diffusion coefficient. No *a priori* way of predicting this is available.

If one assumes that diffusion is by the vacancy mechanism, with maintenance of equilibrium or near equilibrium of vacancy concentration, and with no sensible voids created, then self-diffusion measurements in alloys might possibly be taken to predict the direction of movement of markers; from Johnson's results on self-diffusion coefficients in a 50:50 atomic pct Ag-Au alloy,<sup>18</sup> it would then be predicted that the marker would move toward the silver side of the couples, which indeed it is observed to do in the experimental work given above. Whether self-diffusion coefficients in the pure components could be used somewhat similarly cannot be said, for such coefficients are either not available, or too uncertain in accuracy, or not applicable (as in the case of Zn, where the data apply to hexagonal Zn, not to the cubic lattice concerned).

### Summary

This is an experimental study of the movement of markers during diffusion in solid solutions, the phenomenon discovered by Kirkendall. Six systems have been investigated, at a series of temperatures: Cu/ $\alpha$ -brass; Cu/Sn $\alpha$ -solid solution; Cu/Al  $\alpha$ -solid solution; Cu/Ni; Ag/Au; Cu/Au; diffusion couples have been made by welding. Markers of many types have been used, including W, Mo, Ni, Pt wires; Pt, Ta, Fe, Ni foils; C, Al<sub>2</sub>O<sub>3</sub>, Fe<sub>2</sub>O<sub>3</sub> powders. All markers move, and by the same amount in a given system, the phenomenon is thus not a property of the marker; the movement, with respect to the Matano interface, has been measured for the separate systems. In the Cu/ $\alpha$ -brass couples, the markers move toward the high-Zn side; in the Cu-Al system, toward the high-Al side; in the Cu-Sn system, toward the high-Sn side; in the Cu-Ni system, toward the Cu; in the Ag-Au system, toward the Ag; in the Cu-Au system, toward the Au. Measurements agree reasonably well with Kirkendall's, showing that the technique of joining is unimportant. The Matano interface agrees with the original interface, showing conservation of atoms on lattice sites, and showing porosity to be negligible.

The amount of marker shift differs from system to system, for unexplained reasons; the amount of shift is sometimes near the maximum possible; it is large in Cu-Zn and Cu-Ni systems, smaller in others. Dimensional changes seem to be restricted to the direction parallel to diffusion flow. Cu/ $\alpha$ -brass couples exhibit apparent traces of porosity in the diffusion zone (and anomalously low hardness there), while no such porosity could be found in other systems. Only the vacancy mechanism of

Fig. 60—Microhardness traverse on sample B36, after diffusion, Cu/ $\alpha$ -brass.

Fig. 61—Vacancies (I), coagulating to voids (II and III), resulting in dislocations (IV), and resultant mass flow and marker (small dot) displacement.

diffusion appears to be useful in explaining these phenomena, though several theoretical points remain to be explored. Inasmuch as the amount of shift is independent of the nature of the external surface of the diffusion couple, and of the dimensions of the couple, it appears that operating vacancies cannot come from external surfaces but must be generated within the diffusion zone itself. A dislocation mechanism is proposed to explain marker shift.

### Acknowledgment

We wish to express our gratitude to the Office of Naval Research for support of the experimental work; to the Instituto de Pesquisas Tecnológicas of São Paulo, Brazil, for having generously supplied a fellowship to one of us; and to C. E. Birchenall and other members of the staff of the Metals Research Laboratory for advice and help.

# Effect of Ternary Additions on the Age-Hardening Of a Copper-Silver Alloy

by Harold Margolin and Walter R. Hibbard, Jr.

The effect of ten ternary additions on the aging of a Cu-Ag alloy was measured by X ray, microstructure and hardness. A super-saturated copper-rich transition structure was found. The effect of the ternary element was related to differences between transition and precipitate lattice parameters and analogies with solution and strain hardening.

IN addition to the prerequisite of diminishing solid solubility with falling temperature, the theory of coherency hardening<sup>1</sup> proposes that the principal source of hardening during precipitation is strain caused by coherency between the matrix and precipitate. For a given system greater coherency hardening would result from lengthening the period of coherent growth and/or increasing the number of nuclei, other things remaining equal. However, the hardness change during aging is a function of a number of phenomena in addition to coherency hardening, such as dispersion hardening, loss of coherency, solute depletion, matrix recovery or recrystallization, coalescence, and their relative time sequences.

Fig. 1—Aging curves for 500°C.

The present investigation was undertaken to study the effect of ternary additions on the age-hardening of Cu-Ag alloy. For this purpose a series of alloys were made containing as ternary constituents Mg, Al, Si, P, Mn, Ni, Zn, As, In, and Sb. These elements were added to a master 5 wt pct Ag in Cu alloy in

Discussion of this paper, TP 3002 E, may be sent (2 copies) to AIME by April 1, 1951. Manuscript, Oct. 16, 1950; revision, Dec. 6, 1950. St. Louis Meeting, February 1951.

This paper is part of a dissertation by Harold Margolin presented in partial fulfillment of requirements for the degree of Doctor of Engineering to Faculty, School of Engineering, Yale University.

Fig. 2—Aging curves for 500°C.

such amounts as to obtain alloys listed in Table II containing the following approximate atomic percentages: 96 pct Cu, 3 pct Ag, 1 pct ternary addition. A 97 atomic pct Cu, 3 atomic pct Ag alloy was used as a comparison standard.

There have been numerous investigations of age-hardening in Cu-Ag alloys<sup>2-10</sup> but few of ternary Cu-Ag alloys. Pfister and Weist<sup>11</sup> found that 1 wt pct Ni reduced the solubility of Ag in Cu above 600°C and that the rate of precipitation was slower than in polycrystalline Cu-Ag alloys of similar silver content. More recently Hodge, Jaffee, Dunleavy, and Ogden<sup>12</sup> investigated the effect of ternary additions of Mg, Li, P, Cd, Zn, Zr and Be on strength properties of Cu-Ag alloys. Mg, Cd, and P were found to increase strength in the aged and cold-worked condition.

## Experimental Procedure

Charges weighing 7.5 lb were melted in a closed carbon crucible under a reducing atmosphere\* of nitrogen and hydrogen. A Durville-type casting procedure with a hot-top arrangement was used to obtain a sound casting, 2x2x4<sup>3</sup>/<sub>4</sub> in. Prior to rolling and annealing of the ingots, a trial solution anneal of rolled sections of the hot-top portions indicated that at 780°C melting was avoided except for the Cu-Ag-Sb alloy. This alloy could not be produced as a single phase within the limits of temperature control,  $\pm 3^\circ$  to  $5^\circ$ C, since melting occurred at 640°C, and below this temperature precipitation was

\* This gas, a nonexplosive reducing mixture containing 93 pct N<sub>2</sub> and 7 pct H<sub>2</sub>, dried by passing through H<sub>2</sub>SO<sub>4</sub>, was also used in all annealing and aging treatments.

Table I. Lattice Parameters for Various Alloys

| Alloy     | Cu, A  | Ag, A | Cu Transition, A | Aging Time at 550°C, Hr |
|-----------|--------|-------|------------------|-------------------------|
| Cu-Ag     | 3.6137 | 4.069 | 3.658            | 90                      |

| Cu-Ag-Sb  | 3.6194 | 4.065 | 3.668            | 24                      |
| Cu-Ag-In  | 3.6151 | 4.103 | 3.710            | 24                      |
| Cu-Ag-Mg  | 3.6132 | 4.068 | 3.670            | 29.5                    |
| Cu-Ag-Mn* | 3.6130 | 4.074 | 3.656            | 29.5                    |
| Cu-Ag-Ni  | 3.6114 | 4.073 | 3.653            | 29.5                    |
| Cu-Ag-P   | 3.6129 | 4.066 | 3.655            | 24                      |
| Cu-Ag-Sb  | 3.6236 | 4.082 | 3.662            | 44                      |
| Cu-Ag-Si  | 3.6131 | 4.068 | 3.654            | 44                      |
| Cu-Ag-Zn  | 3.6142 | 4.072 | 3.648            | 24                      |

\* In addition to the silver and transition copper lines, other unidentified lines were seen.

found. Prior to the final solution treatment the alloy was not heated above 630°C.

Specimens for hardness tests were produced by step-wise cold rolling and annealing longitudinally split sections of the casting, approximately 1 in. thick, to a common thickness of 0.165 in. and thence in two reductions of 30 pct each to a final thickness of 0.080 in. Wire specimens for lattice parameter measurements, prepared by a schedule similar to that for hardness specimens, were 0.077 to 0.080 in. in diam. These wires were not etched. Both hardness and lattice parameter specimens were in the cold-worked state prior to the final solution treatment.

With the exception of Cu-Ag-Mg, which was annealed at 800°C, and Cu-Ag-Sb, which was annealed at 650° to 675°C, the alloy specimens 1x $\frac{3}{8}$ x 0.080 in. were solution-annealed from 24 to 48 hr at 775°C and quenched in water.

A Rockwell hardness tester, fitted with a 136° diamond pyramid penetrator and a total load of 27.6 kg was employed to obtain the diamond pyramid hardness values.

Debye-Sherrer X-ray patterns were obtained with copper radiation, monochromated by reflection from a cleavage section of penta-erythritol. Exposures of one to three days were required, and, because of the large grain sizes, rotation of the specimens did not always eliminate spottiness. Lattice parameters based on the 420  $K\alpha_1$  and  $K\alpha_2$  and the 331  $K\alpha_1$  and  $K\alpha_2$  for the stable copper solid solution were determined by Cohen's method<sup>18</sup> of extrapolation and checked against a  $\cos^2\theta$  extrapolation. Parameters determined by these methods checked within 0.0003A. The errors

Fig. 3—Debye-Sherrer pattern of Cu-Ag-Al aged 24 hr at 550°C.

in the transition copper parameters based on the 420  $K\alpha_1$  and 331  $K\alpha_1$  lines and the silver parameters determined from the 333 reflections are estimated to be  $\pm 0.0025$  and  $\pm 0.002A$ , respectively.

### Evaluation of Quenching Conditions

The as-quenched hardness of the alloys varied considerably from 52 for Cu-Ag to 69 for Cu-Ag-In. Hardness tests and microscopic examination of three specimens selected at random from a group of 24, which had simultaneously been solution annealed and quenched, and three specimens individually suspended but otherwise given the same treatment, indicated that the quenching conditions were constant within the errors of hardness measurement and random selection of specimens.

### Hardness Deviations

In general each hardness value was obtained by averaging the hardness of three specimens upon which four impressions each had been made, a total of 12 values. The as-quenched hardness values varied very little. However, in some aged specimens deviations occurred up to 33 DPH points, which exceeded the maximum measurement error of  $\pm 2$  DPH points.

An analysis of the hardness data revealed no correlation with grain size or temperature of treatment. However, the deviations in intermediate (Cu-Ag-Ni) and high (Cu-Ag-P and Cu-Ag-Mg) hardness alloys were greater than those in the low hardness alloys (Cu-Ag-Si and Cu-Ag-Zn). This suggests that hardening did not take place uniformly in all ternary Cu-Ag alloys exhibiting high hardness and having intermediate to large grain size.

### Experimental Data

Aging treatments were carried out at 350°, 400°, 450°, and 500°C. Typical hardness vs. time curves obtained for aging at 500°C are shown in Figs. 1 and 2. Debye-Sherrer patterns were obtained from specimens overaged at 550°C for periods of 24 to 90 hr. Films, shown in Fig. 3, of all overaged alloys revealed three sets of lines, two of which were clearly identifiable as (a) intense Cu solid solution lines and (b) broad less intense Ag solid solution lines. The third fainter set of lines was displaced from the intense Cu rings, so as to correspond to reflections from a greatly expanded and probably transitional copper-type lattice. Calculations of lattice parameters on this basis are given in Table I. Lines due to the unstable, supersaturated Cu solid solution appeared for all alloys after aging at 550°C, even after 90 hr at temperature for binary Cu-Ag.

To determine the source of the expanded copper lattice, X-ray exposures were made of Cu-Ag in the solution annealed and in the aged conditions. The pattern obtained after a 120 hr solution anneal and quench, shown in Fig. 4, disclosed only sharp copper lines. After this specimen was given a 20 hr overaging treatment at 550°C, transition copper and

Fig. 6 (left)—Effect of lattice parameter difference on the adjusted age-hardening increment for 500°C.

Fig. 7 (right)—Same as Fig. 6 for 450°C.

silver lines appeared in addition to the stable copper solid solution lines, see Fig. 5. Thus the expanded lattice producing the transition copper lines is formed during aging, probably the result of segregation of silver beyond the equilibrium solubility limits, which would be a logical step in the formation of silver precipitate and the transition phase.

### Distribution of the Third Element

With the exception of the lattice expansion found in Cu-Ag-In and Cu-Ag-Sb, the silver precipitate parameters show changes which lie within the limits of error of measurement. However, this is in contrast to the transition copper lattice parameters, which experience the greatest changes, and the stable copper solid solution matrix lattice parameters. There appears to be no general correlation between expansion or contraction of the transition lattice parameters and those of the copper matrix or between the variations of copper matrix and silver lattice parameters. The changes in parameter of the silver and transition copper in the ternary alloys are unpredictably greater or less than the change in the Cu-Ag alloy, indicating that the third element does not always act to cause closer matching between the silver and transition copper phases which are assumed to be coherent during the early stages of growth of the silver precipitate.

Where the third element does not affect silver lattice parameters, but is probably present in the transition and/or the stable copper solid solution,

Fig. 8 (left)—Same as Fig. 6 for 400°C.

Fig. 9 (right)—Same as Fig. 6 for 350°C.

changes in their lattice parameters may be the result of a redistribution of the third element after silver has precipitated. Variations in the transition copper lattice may be caused, in the case of expansion, by local concentration of the third element. A contraction of this lattice, however, may result from diminished solubility of silver in the transition structure.

### Maximum Hardness

Since the precipitation mechanism of this series of alloys is similar, it would appear that the maximum hardness values should be related to the degree of matching or difference between the lattice parameter of the silver and the transition copper phases. Since the recrystallization phenomenon is less significant at higher aging temperatures,<sup>10, 14</sup> this relationship would be more distinguishable for the data at these temperatures. Plots of maximum hardness at 450° and 500°C vs. parameter difference indicate that as the sizes of the two lattices converge the hardening increases.

These plots, however, do not take into account small differences in solution hardening nor the variations in the exact atomic composition, see Table II. Therefore, if the difference between the maximum hardness attained by a ternary alloy at any particular aging temperature and the as-quenched Cu-Ag hardness is considered as a measure of the hardness increment added to the basic alloy by the third element, this increment ( $\Delta H$ ) can be extrapolated or interpolated to exactly 1 pct, as necessary.

Table II. Atomic and Weight Percentages of Alloys

| Alloy     | Ag, Wt Pct | 3rd Element, Wt Pct | Ag, Atomic Pct | 3rd Element, Atomic Pct |
|-----------|------------|---------------------|----------------|-------------------------|
| Cu-Ag     | 4.95       |                     | 2.98           |                         |
| Cu-Ag-Al  | 4.88       | 0.48                | 2.92           | 1.14                    |
| Cu-Ag-As  | 4.88       | 1.025               | 2.94           | 0.89                    |
| Cu-Ag-In  | 4.75       | 1.84                | 2.88           | 1.05                    |
| Cu-Ag-Mg  | 4.79       | 0.31                | 2.87           | 0.82                    |
| Cu-Ag-Mn  | 4.83       | 0.84                | 2.90           | 0.99                    |
| Cu-Ag-Ni* | 4.52       | 0.94                | 2.71           | 1.04                    |
| Cu-Ag-P   | 4.76       | 0.45                | 2.85           | 0.94                    |
| Cu-Ag-Sb  | 4.78       | 1.47                | 2.89           | 0.79                    |
| Cu-Ag-Si  | 4.88       | 0.43                | 2.92           | 0.99                    |
| Cu-Ag-Zn  | 4.87       | 0.075               | 2.93           | 0.97                    |

\* The analysis of all alloys except Cu-Ag-Ni was performed by Lucius Pitkin, Inc., New York.

Figs. 6, 7, 8, and 9 show the adjusted values of  $\Delta H$  for the temperatures of aging employed. It can be seen, first, that as the differences between the silver and the transition copper lattices decrease, the hardness increases; second, that several rates of hardness changes are evident; and, third, that these relationships exist for all aging temperatures investigated. Thus, there is good general agreement with predicted behavior, although certain detailed differences in hardness change cannot be correlated with individual parameter difference (e.g., Cu-Ag-Al, Cu-Ag-Si, and Cu-Ag-P) or with periodic sequence of the ternary elements. The hardness values for Cu-Ag-In and Cu-Ag-Sb essentially represent measurements of recrystallized material, since in both cases almost complete recrystallization takes place before the hardness maximum is attained. A comparison of hardness values for certain alloys at 450°C indicated that, depending on the alloy and, possibly, the time of aging, the nonrecrystallized areas were as hard and sometimes harder by from 10 to 20 DPH points as the corresponding recrystallized areas. Guy, Barrett and Mehl<sup>15</sup> have shown that a separate, more rapid rate of hardness change exists for the recrystallized areas in Cu-Be alloys.

The ternary solute elements, arranged in decreasing order of the maximum hardness increment, are P and Mg, Mn, Ni, In, Al, Si, As, Sb, and Zn. Hodge et al.<sup>12</sup> have also found that phosphorus and magnesium strengthen Cu-Ag but find "very little effect on the tensile strength" when 1 to 3 wt pct Zn is added to a 6 pct Cu-Ag alloy.

### Rate of Hardening

Examination of the hardness-time curves indicated that certain alloys consistently hardened more rapidly than others. A correlation similar to that for  $\Delta H$  was found for the time to attain one half maximum hardness and the difference between the lattice parameters of silver and transition copper phases. If, at any particular temperature, the difference between the time for each ternary alloy and the basic Cu-Ag alloy to attain one half maximum hardness is adjusted for exactly 1 atomic pct third element, and these adjusted values are plotted against the difference between the silver and transition copper lattice parameters similar figures also are obtained as shown in Figs. 10, 11, 12, and 13.

It will be seen that in general the data for each temperature are scattered along two straight lines which are included to indicate qualitative trends. With the exception of Cu-Ag-P and Cu-Ag-Mg those alloys hardening most rapidly have the lower ad-

Fig. 10 (left)—Effect of lattice parameter difference on the adjusted time increment for half hardening at 500°C.

Fig. 11 (right)—Same as Fig. 10 for 450°C.

justed maximum hardness increment values. It may be noted that, as the parameter difference increases, the rate of hardening decreases. Moreover, those elements which, when dissolved in copper distort its lattice the least, are generally at the low hardening rate end of their respective lines. This suggests that the rate of age hardening may follow a pattern similar to the rate of strain hardening experienced by binary copper, solid solution alloys. Some data on binary copper alloys are available from Martin,<sup>18</sup> in which the hardness of alloys after constant reduction is plotted against the atomic percent of solute. For the Cu-Ag base alloys, the hardness difference between the unworked alloys and those given 20 and 60 pct reduction have been adjusted to exactly 1 atomic pct solute, and plotted against the parameter difference between silver and transition copper phases. The resulting graphs are shown in Figs. 14 and 15. With the exception of magnesium there is good agreement between Martin's data and the authors', suggesting that the third element dissolved in the transition phase and/or the matrix during coherent growth of the precipitate has a similar

Fig. 12 (left)—Same as Fig. 10 for 400°C.

Fig. 13 (right)—Same as Fig. 10 for 350°C.

effect on coherency hardening as it does on work hardening, i.e., more rapid coherency and work hardening occur with increased lattice distortion. Since the rate of recrystallization is slow in Cu-Ag-P, the high rate of hardening may possibly be the result of a high rate of nucleation and possibly by more extended coherent growth.

The elements, arranged in decreasing order of their influence on the rate of hardening are Sb, As, In, Mg, Si, Zn, Al or Mn, and Ni.

### Microstructure

Examination of specimens mechanically polished and etched with copper-ammonium-chloride was principally confined to hardness specimens aged at 450° and 500°C and lattice parameter specimens aged at 550°C. The observed phenomena may be classified in the sequence in which they occur, (a) precipitation within the grain, (b) grain boundary reaction, and (c) coarsening of precipitate.

**Precipitation Within the Grain:** The procedure employed in obtaining hardness-time curves was to use individual specimens for several different accumulative isothermal aging times at a given temperature. Accelerated precipitation occurred in slipped regions around hardness impressions. Fig. 16 shows one of these areas in a specimen of Cu-Ag-P aged

Fig. 14 (left)—Effect of lattice parameter difference on the adjusted work-hardening increment for 20 pct reduction.

Fig. 15 (right)—Effect of lattice parameter difference on the adjusted work-hardening increment for 60 pct reduction.

approximately to maximum hardness after  $1\frac{3}{4}$  hr at  $450^{\circ}\text{C}$ .

Fig. 17 shows a type of structure which at  $450^{\circ}\text{C}$  is common to all alloys except Cu-Ag-P, Cu-Ag-As, Cu-Ag-In, and Cu-Ag-Sb. The interior of grains are subdivided by irregular boundaries. It was suspected at first that these boundaries might be a freak etching effect. A specimen of Cu-Ag-Al was polished and etched with copper-ammonium-chloride, and these lines were developed. The specimen, repolished and etched with ammonium persulphate, did not reveal these boundaries. However, when the as-ammonium-persulphate-etched specimen was re-etched with the first etchant the sub-boundaries, together with the precipitation associated with hardness impressions, reappeared.

These lines are similar in appearance to grain boundaries. Both regions are bordered by a light etching area which suggests that silver, at least, must diffuse from these light etching regions to the boundaries in order to precipitate. The internal boundaries differ from grain boundaries in that the recrystallization phenomenon rarely begins in these areas, although it is often seen at grain boundaries. The two also differ in that the subboundaries enclose regions differing slightly in orientation, as shown by Fig. 17.

It is possible that the internal boundaries were formed prior to aging and that precipitation in these boundaries reveals them. Wood and Rachinger<sup>17</sup> working with aluminum found similar structures which were best revealed by slow deformation at high temperatures, conditions which did not apply in the present study. Intra-grain boundaries readily seen as comparatively short aging times were less distinguished in some specimens of the same alloy aged longer times at  $450^{\circ}\text{C}$ . The internal subdivisions are not at all evident in lattice parameter specimens aged at  $550^{\circ}\text{C}$ . Possibly an explanation of this phenomenon may require consideration of a time-temperature-supersaturation relationship.

A Widmanstätten structure was found in all alloys, but for Cu-Ag-In, Cu-Ag-Sb, Cu-Ag-As, and Cu-Ag-P only in the lattice parameter specimens aged at  $550^{\circ}\text{C}$ . The structure of Cu-Ag-P was most difficult to resolve, a fact which suggests that the high hardness of this alloy may be due to a high rate of nucleation. A Widmanstätten structure was seen before maximum hardness in several instances (Cu-Ag, Cu-Ag-Mg, Cu-Ag-Si, and Cu-Ag-Zn) and

most likely represents localized overaging. No attempt was made to identify the planes of precipitation, but where the precipitate was clearly resolvable no more than three directions of plates were seen.

**Grain Boundary Reaction:** The grain boundary or recrystallization reaction occurred early in the precipitation process and was found to diminish in amount as the aging temperature increased. At high magnifications or where the precipitate was coarse, the recrystallized regions showed a pearlitic-like arrangement of phases.

The procedure of aging and hardness testing adopted afforded some opportunity to observe the effect of cold work on the recrystallization reaction. Generally more recrystallization was revealed near and within the hardness impressions, although the extent varied from alloy to alloy. Fig. 18 shows a region near a hardness impression in which recrystallization has begun, but the direction of most rapid growth is not along the most severely deformed directions. On the other hand, Fig. 16 reveals an instance where growth proceeds along deformation lines in regions of high energy. Therefore, it appears likely that there is an orientation as well as energy dependency for this type of recrystallization.

It was observed frequently during use of the Tukon microhardness tester that slip lines (emanating from hardness impressions) within a given grain changed direction upon entering the recrystallized areas associated with this grain. In some regions traversing slip lines disclosed twins, as shown in Fig. 19.

**Coarsening of Precipitate:** During growth of the recrystallized grains at  $450^{\circ}\text{C}$  the silver particles within them grew resolvable and the spacing between the particles increased. The transition was quite gradual and no boundaries between the two regions could be seen. However, in Cu-Ag alloys aged  $9\frac{1}{2}$  hr at  $450^{\circ}\text{C}$  the coarsening of silver commenced at the recrystallized grain boundaries, as shown in Fig. 20; and in Cu-Ag-In, also aged  $9\frac{1}{2}$  hr at  $450^{\circ}\text{C}$ , at the original grain boundaries as well, although the specimen is almost entirely recrystallized. At 1500X, as shown in Fig. 21, it can be seen that the new precipitate tends to form perpendicular to the advancing interface as in growing pearlite nodules.<sup>18</sup> Some lattice parameter specimens, aged at  $550^{\circ}\text{C}$ , particularly Cu-Ag, also revealed the

Fig. 18 (left)—Cu-Ag-P previously hardness tested and aged  $1\frac{3}{4}$  hr at  $450^{\circ}\text{C}$ . Copper-ammonium-chloride etch. X100.  
Recrystallization at hardness impression.

Fig. 19 (right)—Cu-Ag aged  $3\frac{1}{2}$  hr at  $450^{\circ}\text{C}$ . Copper-ammonium-chloride etch. X500.  
Twins outlined by slip lines in recrystallized grains.

coarsening phenomenon. At  $450^{\circ}\text{C}$  the coarsening reaction occurred primarily at the original grain-recrystallized grain interface, whereas the reaction in the parameter specimens took place primarily at recrystallized boundaries. The general characteristics of the coarsening phenomenon at the recrystallized grain boundaries suggest that a second re-orientation of the precipitate may be taking place.

### The Precipitation Reaction

Precipitation in Cu-Ag and ternary Cu-Ag alloys appears to include the following phenomena:

1. Segregation of silver (and third element where involved) beyond equilibrium solubility limits† in the case of Cu-Ag, and probably in the ternary alloys as well, to form a transition copper-base structure rich in silver
2. Limited coherent growth of the precipitate, involving coherency possibly between precipitate and transition copper lattice and coherency between transition copper and the matrix copper lattice poorer in silver
3. Breaking away of the precipitate, recrystallization, and coarsening

It is entirely possible that the silver precipitate during its coherent growth may exist in a transition form, the entire mechanism thus being similar to that described by Geisler and Newkirk<sup>20</sup> for per-

manent magnet alloys. However, no evidence was found relating to a transition silver-base lattice.

The existence of the transition lattice for extended periods of time at relatively high temperatures may be rationalized on the basis of the experimental fact that large Widmanstätten plates form before maximum hardness is attained. This suggests that coherency does not extend for long times, since loss of coherency and growth of the precipitate in some areas must occur quite rapidly, even before the coherent precipitate is formed in other areas. In view of the sluggishness of the diffusion of silver in copper and the reduction of supersaturation during precipitation, a marked reduction in rate of precipitation during its latter stages might be expected. Evidence of an expanded copper phase on films of all specimens aged at  $550^{\circ}\text{C}$  lends support to this suggestion. Another possible reason for the existence of transition copper lines is connected with the occurrence in certain alloys of the second recrystallization or coarsening phenomenon which must involve resolution and reprecipitation of the silver phase.

† Minimum size of transition copper lattice was measured at  $3.648\text{\AA}$  (Cu-Ag-Zn), and for the transition phase of Cu-Ag the parameters were measured as  $3.658\text{\AA}$ . The lattice parameter of copper containing the maximum equilibrium content of 4.87 atomic pct Ag<sup>10</sup> is  $3.633\text{\AA}$ . Based on the assumption that Vegard's law holds in this enforced solid solution, the silver contents of the transition phases of Cu-Ag-Zn and Cu-Ag are approximately 8 and 10 atomic pct, respectively.

Fig. 20 (left)—Cu-Ag aged  $9\frac{1}{2}$  hr at  $450^{\circ}\text{C}$ . Copper-ammonium-chloride etch. X500.  
Coarsening phenomenon beginning at recrystallized grain boundaries.

Fig. 21 (right)—Cu-Ag-In lattice parameter specimen aged 24 hr at  $550^{\circ}\text{C}$ . Copper-ammonium-chloride etch. X1500.  
Coarsening reaction. (Oblique illumination)

The recrystallization phenomenon appears to be associated with internal stress, for this process occurs most readily in areas immediately surrounding hardness impressions and at low temperatures where hardness and related internal stresses are greatest. When aging temperatures are raised, the extent of recrystallization diminishes and in Cu-Ni-Co<sup>20</sup> and Cu-Ag<sup>21</sup> alloys the phenomenon can be completely suppressed by slow cooling. In experiments on Cu-Be tri-crystals, Guy, Barrett, and Mehl<sup>16</sup> have shown that during aging at 200° and 300°C cracking occurs along grain boundaries where the recrystallization reaction has occurred. No further grain boundary precipitation took place after the formation of cracks, and if aging was carried out at 400°C, no cracking occurred.

Jones, Leech and Sykes<sup>10</sup> have suggested that recrystallization, i.e., discontinuous precipitation, takes place when the temperature is low and the supersaturation high, and that continuous precipitation is prevalent at high temperatures when supersaturation is low. The necessary definitive experiment, i.e., aging alloys of the same constituents but of different compositions at temperatures where the respective degree of supersaturation is the same, has not been performed. Indeed, considerable information is lacking as regards the observed coarsening reaction, subsequent to recrystallization. A program of study involving microstructure examination of large grained specimens during aging and possibly orientation relationships between recrystallized and unaltered areas<sup>22</sup> would probably disclose useful information concerning both phenomena.

### Summary

1. A transition copper-base structure, quite rich in silver, has been found during aging in all the investigated alloys, which are Cu-Ag, Cu-Ag-Al, Cu-Ag-As, Cu-Ag-In, Cu-Ag-Mg, Cu-Ag-Mn, Cu-Ag-Ni, Cu-Ag-P, Cu-Ag-Sb, Cu-Ag-Si, and Cu-Ag-Zn.

2. The ternary elements do not generally appear to be distributed in such a manner as to bring about a closer matching between the silver precipitate and the transition copper lattices. The lattice parameters of the transition phases are most affected by the presence of the third element, whereas with exceptions of Cu-Ag-As, Cu-Ag-In, Cu-Ag-N, and Cu-Ag-Sb the parameters of the copper solid solution and the silver precipitate are relatively unchanged.

3. In general, the maximum increment of hardness, adjusted to exactly 1 atomic pct third element, increases with diminishing difference of the silver and transition copper lattice parameters.

4. Rates of hardening, adjusted for exactly 1 atomic pct third element, generally show an increase with decreasing difference between the silver and transition copper parameters. Those ternary elements, which cause the greatest solution hardening in binary copper alloys, effect the most rapid response to coherency and strain hardening.

5. Microstructure examination has revealed precipitate in Widmanstätten form, along intra-granular boundaries, and in recrystallized nodules prior to attainment of maximum hardness. The intra-granular boundaries differ from grain boundaries in that the former do not appear to enclose regions differing widely in orientation and do not serve as sites at which recrystallization begins. It is also seen that the recrystallization phenomenon, commencing almost completely at grain boundaries, is followed by a coarsening reaction, which is seen at the inter-

faces between recrystallized and nonrecrystallized grains and at recrystallized grain boundaries.

### Acknowledgment

The authors wish to thank Marritt L. Kronberg, who designed and put into operation the monochromating system without which much of the X-ray data could not have been obtained. One of the authors also wishes to express his appreciation to the International Nickel Co., Inc. under whose fellowship this work was carried out.

# El Paso Refinery Of Phelps Dodge Refining Corporation

by B. B. Kunkle

The history of this refinery has been one of expansion. It now has the capacity to produce 240,000 tons of cathodes annually. A general flowsheet and descriptions of the plant layout, operations involved, and equipment used at one of the world's largest and most modern electrolytic copper refineries are presented.

THE El Paso copper refinery of Phelps Dodge Refining Corp. was originally constructed by the Nichols Copper Co., in association with Phelps Dodge Corp. and the Calumet & Arizona Mining Co., in order to refine anode copper produced at the smelters of the two latter companies.

Initial production was obtained from the plant in January 1930 and its annual refining capacity was 100,000 tons of anodes.

In order to keep pace with Phelps Dodge Corp.'s increasing copper production in the Southwest, it became necessary in 1937 to increase the El Paso plant's refining capacity to 160,000 tons of cathodes annually. This was accomplished by adding two sections to the electrolytic tank house, increasing the number of anodes placed in each commercial electrolytic tank from 33 to 37, and making changes in the dc circuits which made it possible to put three generators on each of the two circuits instead of two, thus increasing the amperage on each circuit from 10,000 to 14,800 amp. The capacity of the two furnaces from which refined shapes were cast was increased by raising the sidedoor bays on the furnaces 6 in.

An increase of 70 pct in the productive capacity of Phelps Dodge Corp.'s Morenci Branch in 1942 again made it necessary to expand refining capacity. In order to accomplish this, Defense Plant Corp. set up a project to increase the capacity of the El Paso plant to 240,000 tons of cathodes annually. This project consisted of enlarging the tank house approximately 50 pct, the construction of another wire-

bar furnace, and corresponding increases in other departments where necessary. The engineering work on this expansion was begun in March 1942. Actual construction was under way by August 1942, and the work was completed by March 1944. These additional facilities were purchased from Defense Plant Corp. by Phelps Dodge Refining Corp. in August 1949.

The plant is in El Paso about eight miles east of the center of the city and near Highway 80 and the main lines of the Southern Pacific and Texas & New Orleans railroads. The plant site covers approximately 494 acres of company-owned land that is ideally adapted for its use, being well-drained sandy soil and having enough slope so that a minimum amount of excavation was required when the plant was constructed. There is still ample room on the plant site for any future plant expansion.

The plant is constructed on four different ground levels and so arranged that the unrefined copper is unloaded on the highest level at the north side of the plant and the refined copper is shipped out from the lowest level on the south side of the plant. The receiving or unloading platform, weighing and sampling rooms, main floor of the tank house, acid and condensate storage tanks, and the slimes and copper sulphate plants are on the first or highest level. The tank house basement, yard scales, charging and furnace bays, balloon flue and stack, brick-storage building, substation and power house, boiler feedwater treating plant and pump house, water storage tanks, and change houses are on the second level. This second level also contains ample yard area for setting-up furnace charges, and for storage of custom scrap, cathodes, scrap anodes, blister, coke, and poles. The casting wheels, inspection conveyors, cathode shears, wire-bar scalping machine, slag

B. B. KUNKLE, Member AIME, is Plant Metallurgist, Phelps Dodge Refining Corp., El Paso, Texas.

Discussion of this paper, TP 3010D, may be sent (2 copies) to AIME by May 1, 1951. Manuscript, Oct. 2, 1950. St. Louis Meeting, February 1951.

Fig. 1—Flowsheet of El Paso Refinery.

dump, and shipping department are on the third level. There is also a storage area on this third level, adjacent to the casting building, for storing moulds and refined shapes. The warehouse, machine shop, laboratories, engineering and administrative offices, personnel offices, first-aid station, water-cooling ponds and pump house, and parking lots for the employees are on the fourth or lowest level.

Transportation of materials into and out of the plant, except for the small amount trucked in, is by means of a main spur from the Southern Pacific railroad and six side spurs to various parts of the plant. Transportation of copper between the various departments in the plant is by means of a 30-in. gage track system using locomotives powered with electric motors or combustion engines. A general flow-sheet of the plant is shown in Fig. 1.

### Receiving and Sampling

The copper refined at the plant consists of anode copper produced at Phelps Dodge Corp.'s three smelters in Arizona, blister copper produced at Magma Copper Co.'s smelter in Arizona, and No. 1, No. 2, and Light custom scrap copper received from dealers throughout the western part of the United States.

All anode and blister copper is unloaded, weighed, and sampled by the receiving department. This copper is delivered to the plant in or on standard gage box or flat cars, these cars being spotted on a spur adjacent to and paralleling the receiving platform. The receiving platform, adjacent to the north side of the tank house, is approximately 662 ft long and 91 ft wide, and is paved with concrete. This area provides ample space for the six unloading stands, two 20-ton track scales, drilling and sampling rooms, and storage for anodes.

The anodes are unloaded, by means of hand trucks and air hoists, from the railroad cars into anode rack cars that hold the same number of anodes that are loaded into a commercial electrolytic tank. After the anodes are loaded into the anode rack cars, the net weight of the copper in each one is determined carefully. The cars containing the anodes that are not sampled are taken directly into the tank house for unloading into the electrolytic tanks, or unloaded and placed in stock according to requirements. The

cars containing the anodes that are to be sampled are stored on tracks east of the drilling room in an area provided for that purpose. After these anodes have been drilled, they are handled in the same manner as the others.

Blister copper is unloaded by stacking it on the floor of the anode rack cars, about 50 pieces in each car. After weighing and sampling, this copper is delivered to the yard for unloading into storage or transferring to cathode flat cars for charging to the anode furnace.

The drilling room is equipped with air hoists for handling the copper and three drilling units. A separate room is provided for grinding, screening, quartering, and otherwise preparing the samples for the laboratory. All drilling is done according to carefully designed templates.

### Custom Scrap

Custom scrap is received in a yard area east of the receiving department and is serviced by a standard gage railroad siding that also serves the blue vitriol plant. The copper scrap is unloaded on an area, 40x250 ft, paralleling the tracks and paved with reinforced concrete. An unpaved area to the east provides space for burning insulated wire.

After unloading, the copper scrap is sorted and classified according to the best established refinery practice. Only No. 1, No. 2, and Light copper is accepted. It is then sampled, baled, and weighed. No. 1 copper is charged to the wire-bar furnaces, and No. 2 and Light copper is charged to the anode furnace.

### Electrolysis

The multiple-system tank house consists of one large room that has an east-west length of 775 ft and a north-south width of 328 ft, thus covering an area of nearly 6 acres. The building has red hollow-tile walls and a cast-gypsum roof, the top of the roof being protected with Barrett specification roofing. The walls and floor of the basement, as well as the main working floor, are concrete. The building has three monitors in the roof which extend the entire length of the building. The center monitor has 25 Robertson ventilators which provide natural ventilation. Large, continuous windows in both the walls and monitors provide ample natural light during the day. Hinged sections in these windows provide a means for greater ventilation during the summer months. The maximum, inside height of the monitors above the working floor is approximately 41 ft. The electrolytic tanks are separate from the working floor, and both are supported by concrete columns in the basement. The clearance between the basement floor and the working floor is approximately 7 ft.

There is one central pump bay 36 ft wide extending the entire length of the tank house. This bay has a maximum depth of approximately 15 ft below the level of the working floor and contains the sumps, pumps, head tanks, storage tanks, and other equipment required to handle the electrolyte and slimes.

There are two crane bays on each side of and parallel to the pump bay. Each of these four crane bays, which contain the electrolytic tanks, are 73 ft wide and are equipped with a total of seven overhead, two-hook cranes; namely, two 15-ton Shaw-Box cranes and five 12½-ton Milwaukee cranes. A No. 14 Bedford transfer crane, at the east end of the tank house, is provided for transferring cranes from

one crane bay to another. These cranes are used for placing anodes into and removing anode scrap and cathodes from the electrolytic tanks, stripping operations, and handling starting-sheets and suspension bars.

The electrolytic tanks are constructed of reinforced concrete 5 in. thick, adjacent tanks having a common wall, and they are lined with 8-lb, 6 pct antimonial lead. The inside dimensions of each tank, after the lead lining is in place, is about 13 ft 2¼ in. long, 43 in. wide, and 46 in. deep. Thirty-two, 2-in. fiber-conduit weep holes are spaced equally in the bottom of each tank so that leaks in the lead lining can be detected quickly. The tanks are supported by reinforced concrete columns capped with 1-in. thick glass plates.

There are 38 sections of 32 tanks each and 17 sections of 36 tanks each, making a total of 55 sections and 1828 electrolytic tanks. Normally, 52 sections having a total of 1728 tanks are used for producing commercial cathode copper, and 3 sections having a total of 100 tanks are used for producing starting-sheets. The 32 tank sections have two rows of 16 tanks each and the 36 tank sections have two rows of 18 tanks each. The commercial electrolytic tanks have a capacity of 37 anodes and 38 cathodes, the spacing between anodes is 4 in. The starting-sheet electrolytic tanks have a capacity of 34 anodes and 33 starting-sheet blanks, the spacing between anodes is 4½ in.

The Whitehead single-contact system is used and a Baltimore groove is cast in the top of the positive lug of each anode. Three electrical circuits are used: No. 1 consisting of 2 starting-sheet sections and 18 commercial sections, No. 2 consisting of 18 commercial sections, and No. 3 consisting of 1 starting-sheet section and 16 commercial sections. The average maximum current density used on each of the three circuits is about 20.5 amp per sq ft. The average voltage measured across each commercial section is about 6 v.

The electrolyte is separated into five separate circulations or liquor circuits. Two of these liquor circuits have 16 commercial sections on each of them, while the other three have 8 commercial, 8 commercial and 1 stripper, and 4 commercial and 2 stripper sections on them, respectively. A total of 15 Worthington centrifugal pumps are provided for pumping the electrolyte. Eight of these pumps are used normally for circulation purposes, three are standby pumps, and four are used for pumping into or out of storage tanks. Ten of the pumps are the vertical type and the balance are the horizontal type. The circulation of the electrolyte through the electrolytic tanks is from bottom to top in a longitudinal direction at an average rate of 4 to 5 gpm.

Seven, single-pass floating-head Karbate heaters made by the Chemical Equipment Manufacturing Co. have been installed recently to heat the electrolyte, the electrolyte passing through these heaters while it is being pumped from the sumps to the head tanks. These heaters consist of a bundle of tubes made of Karbate through which the electrolyte passes, the tubes are enclosed in a lead-lined steel shell into which steam is injected. The 1-in. diam lead-pipe coils in the sumps, formerly used for heating the electrolyte, are now used only for standby and occasionally auxiliary heating purposes. The temperature of the electrolyte in the head tanks is maintained at approximately 145°F.

The addition reagents added to the electrolyte

consist of glue and sodium chloride. Excess copper is removed from the electrolyte by means of electrolytic tanks in the commercial sections loaded with insoluble lead instead of copper anodes. The free sulphuric acid content of the electrolyte is maintained by the additions of 66 Bé H<sub>2</sub>SO<sub>4</sub> and distilled water. The amount of impurities in the electrolyte are controlled by withdrawing solution from the liquor circuits and sending it to the blue vitriol plant where it is used for making commercial grades of copper sulphate.

The electrolyte contains an average of about 3.5 pct Cu, 17.5 pct free H<sub>2</sub>SO<sub>4</sub>, and 0.0025 pct Cl. Sufficient addition reagents are added to the electrolyte to produce a smooth cathode that is not too hard.

The commercial anodes have a body 36 in. sq and weigh approximately 690 lb. Stripper anodes, cast in the El Paso refinery, have a body 38 in. wide and 37½ in. high, and weigh approximately 840 lb. Starting-sheets are 37½ in. sq and the average weight is about 11½ to 12 lb without the loop.

The average anode cycle is about 26 days. The average commercial cathode cycle is about 13 days. Starting-sheets are stripped daily.

Normally, the commercial sections are operated with one side charged with new anodes and the other side charged with half-run anodes. Thus, the anode scrap must be removed from one side of the section, the slimes cleaned out of the tanks, and new anodes loaded into them each time the cathodes are pulled from both sides. Anode scrap is pulled from one side of each stripper section every two weeks.

Starting-sheets are looped with a single loop 18 in. wide, threaded with a suspension bar, and placed in racks in the same areas where the stripping is done. The racks of starting-sheets then are placed on top of the sections where they are required. The sheets are flapped dry on stainless steel flapping boards and placed in the tanks by hand after the anodes are in place. This is the only flapping that is done. Metermen and hot-sheet men work daily on top of the sections eliminating the short circuits that occur between the anodes and cathodes.

Four cathode washing machines, two on each side of the pump bay, are in the basement. The cathodes are loaded into these washers with the cranes through openings in the working floor. Chain conveyors carry the cathodes in a vertical position through these washers while hot distilled water under high pressure is sprayed on them. When the cathodes are discharged from the washers, they fall in a flat position on cathode flat cars and are ready to be hauled to the yard for weighing.

Openings in the working floor also are provided for loading anode scrap, after it has been washed free of slimes, upon cathode flat cars in the basement so that it can be removed to the yard for weighing.

The tank house slimes, which contain the precious metals and other insoluble anode impurities, are collected in a separate launder system when they are cleaned from the electrolytic tanks. After screening through a 35-mesh screen, these slimes are pumped in the form of a slurry to storage tanks in the basement of the slimes treating plant.

### Slimes Treating Plant

The building is 100 ft east of the tank house and consists of a 19x54-ft main building with four floors and a basement and a 38x39-ft south extension with a main floor and basement, the basements are on the same level as the tank house basement. The walls

are made of red hollow tile. The main building has air-tight windows made of glass blocks, the inside walls have a smooth coating of plaster, and the reinforced concrete floors are all sloped and provided with drains so they can be washed.

The main building is ventilated with a large blower. The suction of this blower is connected to pipes that extend to and have one or more openings on each floor. Dampers are located near each opening so that flow of air into them can be regulated. Air is drawn into the building on each floor through adjustable louvers in the walls. The air from the blower is discharged into a scrubber where any dust that may be in the air is removed with water before it is discharged to the outside. This method of ventilation prevents the loss of any dust.

Copper is present in the tank house slimes in the form of metallic copper and copper selenide and telluride. The purpose of the slimes treating plant is to reduce the copper content of the slimes to 3.0 pct or less. This is accomplished by aeration in tank house electrolyte.

The slimes slurry pumped from the tank house to the three storage tanks in the basement is allowed to settle. The clear liquor is returned to the tank house and the thickened slurry is pumped to tanks on the top floor of the building where further thickening is accomplished by settling and decantation. The resulting heavy slimes slurry is charged to four leaching tanks, on the same floor, that previously have been charged with tank house electrolyte. These lead-lined wooden tanks are about 6½ ft sq and 13 ft high. Air under 10-lb pressure is introduced into the bottom of each tank through 16 equally spaced ¼-in. diam orifices. Air is supplied with a Fuller rotary air compressor. The charge is heated with live-steam jets. After leaching is completed, the leached slimes again are thickened and then washed free of electrolyte by settling and decantation in five tanks located on the 3rd floor and 2nd floor mezzanine. These slimes then are filtered on a 3x4-ft Oliver drum filter that discharges directly upon a gas-fired Lowden drier, with a 4x27-ft hearth, located on the 2nd floor. The leached slimes are dried to about 10 pct moisture before being discharged into a tilting double-cone mixer, on the 1st floor, from which they are dumped, sampled, and then packaged in iron drums.

All of the liquor from the leaching operations is returned to the tank house after it has been processed to remove small amounts of selenium and tellurium which go into solution. This is a cementation process using tank house stripper scrap.

The packaged slimes are shipped to the United States Metals Refining Co., Carteret, N. J., for further treatment.

### Blue Vitriol Plant

This plant not only provides a means for purifying the tank house electrolyte, but also is capable of producing more than 1100 tons per month of copper sulphate that will assay not less than 99.0 pct  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ .

The building is north of and adjacent to the slimes treating plant. It consists of a 54x115-ft main building with three floors and a basement, a main floor 47x134-ft west extension, a main floor 16x77-ft east extension, and a 40x100-ft quonset storage building. On the north side of the plant is a 15x149-ft shipping platform serviced by a standard gage railroad siding. The walls of the main building are made of

red hollow tile, and the two extensions have R.P.M. siding. All floors are reinforced concrete.

The electrolyte withdrawn from the tank house is stored in two storage tanks in the basement. This electrolyte is pumped to two oxidizing units on the 3rd floor. Each unit consists of two lead-lined steel towers for shot copper elevated so they will drain into a single charge tank. A charge to each unit amounts to about 52,000 lb of electrolyte. The solution is withdrawn intermittently from the charge tank and sprayed into the top of the shot towers, that are filled with shot copper, by means of an air lift operating under a maximum pressure of about 65 lb. Air is blown up through the shot copper under a pressure of about 4 lb. The solution drains down through the shot copper and back into the charge tank. The solution is heated in the charge tank with live-steam jets and circulated in the above manner until the free acid has been neutralized by converting it to copper sulphate, this usually requires about 12 hr per charge. This charge is pumped to a holding tank on the 3rd floor from which it flows by gravity to a filter press on the 2nd floor where the float slimes are removed. The filtered liquor is pumped to one of five atmospheric evaporators on the 3rd floor where it is evaporated to about 49 Bé. Each evaporator is equipped with eight double 100-ft steam coils made of 1-in. diam lead pipe which are operated under 30 lb pressure. Then this liquor is put into atmospheric coolers, one charge from an oxidizer unit ultimately filling a cooler.

The coolers are lead-lined steel tanks. The inside dimensions are about 7½x16½x4½ ft with ends curved on a radius of 3¾ ft and they have a working capacity of about 500 cu ft. There are 16 coolers on the 2nd floor and 15 coolers on the main floor west extension. A total of 180, ¾x48-in. round copper rods are spaced equally and suspended vertically in each cooler on 2x4-in. boards supported by iron tee bars. A drain in the form of a plug seat is provided in the center of each cooler bottom.

The coolers are operated normally on either a six or seven day cycle depending upon production demands, and each cooler will produce an average of about 8 tons of copper sulphate per cycle. About one day of each cycle is required for draining the cooler, cleaning out the copper sulphate crystals that form on the rods, sides, and bottom, and refilling it. When the crystals are removed from the coolers, they are placed in 30-in. gage side-dump cars of about 3000-lb capacity, trammed by hand to a 6000-lb capacity elevator, and taken to the 3rd floor where they are dumped through grizzlies into storage bins, the bottom crystals being kept separate from the rods and sides crystals. The sides and rods crystals are crushed with a finger crusher, screened through a 3x8-ft vibrating triple-deck Niagara screen located on the 2nd floor, in order to separate or grade the crystals according to size, and stored in bins on the main floor from which they are bagged. The bottom crystals are crushed with a saw-tooth crusher, washed and centrifuged dry, and blended with the other crystals on the screens. The bagged crystals are handled and stored on wooden pallets by using a Clark fork-lift truck.

First mother liquors are evaporated to make second crystals, which are also of commercial grade. Second mother liquors are evaporated to make third crystals, which are dissolved with distilled water in an agitator and the solution returned to the oxidizing units. Third mother liquors are sent to cementa-

tion tanks where the copper that remains in solution is removed with iron. The waste liquor is discarded and the cement copper sent to the Phelps Dodge smelter at Douglas, Ariz.

The east main floor extension houses a Raymond No. 32 impact pulverizer equipped with a drier fired with natural gas, cyclone collector, mechanical separator, and Dracco collector. This equipment will convert about 600 lb of blue vitriol per hour into —300-mesh Instant or Monohydrate copper sulphate.

Shot copper for the process is produced at the Douglas smelter from converter copper. It is received in railroad box cars and unloaded through hatches on the shipping platform into storage bins, located in the blue vitriol plant basement. It is trammed to the top of the shot towers by means of bottom-dump 30-in. gage cars and a 5000-lb capacity elevator.

### Casting and Inspection

The building, which houses the casting, inspection and shipping departments, and also the cathode shears and wire-bar scalping machine, is 479 ft long and 207 ft wide and is directly south of the tank house, the charging floor being on the same level as the tank house basement. The intervening yard space, which is 220 ft wide, provides ample room for the two yard scales and setting-up furnace charges. The building has two levels: Namely, the charging and furnace level, and a casting, inspection, shipping, shearing, and scalping level, the difference in elevation is 7 ft. The sides of the building are covered with Tennessee galvanized copper-steel sheathing and the roof is cast gypsum except for the metal roofing directly over the furnaces.

The charging bay is 40 ft wide and is equipped with two 3½-ton Morgan overhead charging cranes and one 5-ton Milwaukee overhead service crane. The pole storage area is outside of the building at the east end of the charging bay. The furnace bay is 24 ft wide. The reverberatory anode furnace has a capacity of 225 tons and is equipped with a 600-hp waste-heat boiler. Two wire-bar furnaces have a capacity of 385 tons each and are equipped with 600-hp waste-heat boilers. A third wire-bar furnace has a capacity of 400 tons and is equipped with a 1200-hp waste-heat boiler.

Anode and wire-bar furnaces have inverted-arch, silica brick bottoms; hard-burned magnesite brick below the metal line; chemically bonded brick in back wall, throat, and uptake; and 15-in. silica brick in the hood and main roof. The verb arch and the supporting arch for the uptake are of magnesite-chrome mixture brick. The buckstays at the charging side are protected by steel water-cooled pads. At the charging doors, two on the anode and three on the wire-bar furnaces, the buckstays are protected from the furnace heat, when the doors are open, by heavy castings bolted to the buckstays. The charging doors, which are water-cooled on the sides and bottom, are lined with fire brick and operated by air hoists. Water-cooled flange steel skewbacks are used on the charging side of the furnaces and cast iron skewbacks on the back wall side. All water used for skewbacks is treated with Calgon and this has minimized scale and skewback failures.

Natural gas, which is used for fuel, is delivered to the plant at 350-lb pressure, is reduced to 35 lb in the meter house and is at about 30 lb when it reaches the furnaces. The anode furnace and two of

the wire-bar furnaces are equipped with Coppus-Dennis burners, two on the anode and three on the wire-bar furnaces. The third wire-bar furnace is equipped with three Tate-Jones, cement-kiln type, low-pressure burners. Two wire-bar furnaces have pre-heaters for raising the temperature of the air for combustion. The combustion air from two 10,000 cu ft forced-draft fans passes through carborundum tubes which are heated by the combustion gases passing around these tubes on their way to the main balloon flue and 410-ft stack. The anode and one wire-bar furnace have bypass or auxiliary stacks that have a height of 78 and 91 ft, respectively, above the charging floor.

The casting and inspection bay, 67½ ft wide, is serviced with two 15-ton overhead Milwaukee cranes and one 15-ton overhead Shaw-Box crane.

Anodes are cast in 20 copper moulds on a 31-ft diam Clark wheel with a single ladle that is controlled electrically. Pulverized silica, 200 mesh, is used to paint the moulds. The copper insert blocks for the Baltimore groove are cast by the furnace crew. Two push pins activated by a toggle arrangement raise the anodes from the moulds. A ½-ton Shaw bosh crane removes the anodes from the moulds and places them on spaced racks in the bosh. An overhead crane removes the anodes from the bosh with a rack similar to the rack used in the tank house. After inspection, the anodes are placed in an anode rack car and transported to the receiving department for weighing and sampling before they are stocked or delivered to the tank house.

Wire bars, ingot bars, and ingots are cast on three 40-ft diam Clark wheels, each having 30 copper moulds and using two ladles, all of which are controlled electrically. The moulds are painted by spraying a water and bone ash emulsion with high-pressure air. The moulds are turned over by means of a dumping-tee mechanism and the cast shapes fall into a bosh pit where they are quenched. An incline conveyor brings the cast shapes up out of the bosh pit to an inspection conveyor where the copper inspectors gage each piece for size and make a rigid inspection for defects. The wire bars are removed from the inspection conveyor with air hoists and loaded on cars which are delivered to the shipping department. Ingot bars and ingots are removed from the inspection conveyor by hand and placed on wooden pallets which are delivered by powered fork-lift trucks to the shipping department. Rejected pieces are placed to one side for remelting.

A mould press on each wire-bar furnace having water-cooled copper wire-bar dies is used to make the copper moulds required for the various sizes of wire bars. A portable tilting ladle is used to cast anode moulds.

A charge for the anode furnace consists of anode scrap from the tank house, blister, ladle scrap, and No. 2 and Light custom scrap. A wire-bar furnace charge consists of cathodes, No. 1 custom scrap, ladle scrap, moulds, warmers, and rejects. The furnaces are operated on a 24-hr cycle. This cycle, which begins early in the afternoon, consists of charging, melting, skimming slag, flapping, covering charge with coke, poling until the copper has reached the required set, and casting the copper into shapes. Flapping is done with iron pipes using air under 20-lb pressure. Poling is with green, hardwood poles.

Fire-refined copper cast into ingots and ingot bars is produced from the wire-bar furnaces by charging

them with carefully selected high-purity copper.

Samples are taken of the castings from all furnace charges and analyses made for Cu, Ag, Au, and impurities. The conductivity of the copper is also determined.

Slags are broken up and stored in an outdoor area at the east end of the shipping bay. They are shipped in gondola cars to the Douglas smelter. Moulds are stored in an outdoor area 82 ft long at the west end of the casting and inspection bay which is serviced by the overhead crane in the west end of this bay.

A building at the eastern end of the yard area between the tank house basement and the charging floor provides storage facilities for stocks of brick, fire clay, silica, bone ash, charcoal, and other supplies for the anode and wire-bar furnaces. This building is of hollow tile construction and is 39x260 ft. A standard gage railroad siding parallels the south side of the building. Coke is stored in an open area east of this building.

A brick-grinding plant, just east of the furnace bay, is equipped with a jaw crusher, Gruendler grinder, Raymond impact pulverizer, and a bag-type dust collector. This equipment is used to grind silica, magnesite, and chrome brick cobbings for furnace repairs.

### Shipping

The shipping bay, south of and adjacent to the casting and inspection bay, extends the full length of the building and is 60 ft wide. This, together with an outside storage area of the same width and 165 ft long, at the west end of the bay, provides ample storage for refined shapes. This bay and storage area is serviced with one Euclid, one P & H, and one Milwaukee overhead crane, each having a capacity of 10 tons. Three track scales of 20-ton capacity each are provided for weighing copper. Two "Ready Power" motor-powered trucks and three Baker trucks powered with Edison batteries, all of which are the fork-lift type, are used for handling palletized ingots and ingot bars and for loading all kinds of refined shapes into railroad cars. A shipping platform 15½ ft wide and 594 ft long is parallel with and adjacent to the south side of the shipping bay and outside storage area.

### Cathode Shears and Scalping Machine

Two Hilles-Jones shears for shearing cathodes are at the east end of the shipping bay. Each shear consists of a large shear for cutting off loops and making the first cut and a small cut-off shear which makes the final cuts. When producing 12½x17½-in. cathodes, each shear will cut 220,000 lb of cathodes per 8-hr shift.

An Ingersoll single head, custom built, scalping machine is also in the shipping bay. This machine will scalp 275—54-in.—wire bars per 8-hr shift. Just enough copper is cut from the set side of the wire bars to remove the roughness which is characteristic and appears at this surface.

### Warehouse and Shops

The warehouse is 69 ft south of the eastern portion of the shipping platform and is of hollow-tile construction. It consists of a building 39x240 ft with an unloading platform 15x220 ft serviced by a standard gage railroad siding.

The shops are 31 ft south of the western portion of the shipping platform and 80 ft west of the warehouse. The building is of hollow-tile construction, is 57x280 ft, and houses the machine, blacksmith,

electrical, and carpenter shops equipped with the machines and tools necessary for the maintenance of a plant of this type.

### Power

All of the electric power for the plant is purchased from the El Paso Electric Co. Alternating current is delivered at 13,200 v and stepped down to 2300 v at the plant substation.

A brick building, 51x144 ft, with the main floor 15 ft above the ground floor, houses the direct-current power generating equipment for electrolysis. The air-conditioning and armature-cooling equipment, bus bars, and switchgear are on the ground floor. The motor-generator sets, control equipment, and four air compressors are on the elevated main floor. This floor is serviced with a 15-ton Bedford overhead crane, and an open bay at the east end of the building facilitates the removal and installation of heavy equipment. The building is located centrally 73 ft south of the tank house.

Direct current is produced with three double unit and two triple unit General Electric motor-generator sets, each dc generator unit having a capacity of 750 kw and an output of 5000 amp at 150 v. A full tank house requires the operation of two double and two triple sets, as each of the three electrical circuits in the tank house require nearly 15,000 amp. The other double set is held as a standby. Except for the motor-generator sets, which operate on 2300 v, practically all of the electric motors in the plant are operated on 440 v. A standard 220-110 v, three wire, single-phase lighting system is used.

The four Ingersoll-Rand air compressors supply compressed air for general plant requirements. Two of these are low-pressure compressors, each having a capacity of 1080 cfm at 40 psi. The other two are high-pressure compressors, each having a capacity of 1210 cfm at 100 psi.

### Water Supply and Treatment

All of the water required for plant operations is obtained from three 700-ft water wells equipped with Layne-Texas turbine-type pumps. These pumps deliver water to three tanks having a total capacity of one million gallons. Two of these tanks are elevated in order to maintain about 30-lb pressure in all of the fresh water lines. An electrically driven pump and one driven with an internal-combustion engine, which is used in case of a power failure, boost the pressure in the water lines to as much as 125 lb for fire-fighting purposes.

All of the water pumped from the three wells is given the Hall Threshold treatment. The boiler feed-water is treated by the Infilco hot lime-soda ash and the Hall system.

### General

The general office building, west of the shops near the main plant entrance, houses the administrative, accounting, and engineering offices, and a well-equipped laboratory.

Another building, at the main plant entrance, houses the time-clock alley, personnel and safety engineering offices, and clinic for first-aid treatment.

# Sulphur Activities in Liquid Copper Sulphides

by R. Schuhmann, Jr. and O. W. Moles

An equilibrium study was made of the reaction:

at temperatures of 1150°, 1250°, and 1350°C for liquid copper sulphides ranging in composition from saturation with Cu to about 21.5 pct S. From the experimental data, activities of Cu, S, and  $\text{Cu}_2\text{S}$  in the melts were calculated. Also, the results furnish a new determination of the location of the curve showing the compositions of Cu-saturated sulphide melts in the Cu-S constitution diagram.

THE "white metal" made as an intermediate product in converting copper matte to blister copper is a matte approximating  $\text{Cu}_2\text{S}$  in composition. It has long been known that liquid Cu-S mattes can exist at a given temperature over an appreciable composition range, with S:Cu ratios ranging up from a lower limit corresponding to equilibrium of the matte with a liquid Cu phase. The Cu-saturated matte has somewhat less S than  $\text{Cu}_2\text{S}$ , although previous measurements of the compositions of Cu-saturated mattes are not in good agreement.<sup>1-4</sup> As the S:Cu ratio approaches and slightly exceeds that for  $\text{Cu}_2\text{S}$ , the partial pressure of sulphur gas over the liquid matte rapidly approaches atmospheric pressure,<sup>5</sup> so that Cu-S melts with much more S than  $\text{Cu}_2\text{S}$  can be made and handled only in pressure apparatus. Accordingly, the liquid copper sulphides of interest in copper smelting and readily studied experimentally fall in a relatively narrow composi-

tion range about  $\text{Cu}_2\text{S}$ . The freezing points of Cu-S mattes show a maximum of 1129°C near the composition  $\text{Cu}_2\text{S}$ , dropping to 1105°C for Cu-saturated mattes having less S and dropping under 1100°C for higher S mattes.<sup>4</sup>

Estimates of the sulphur pressure and other thermodynamic properties of liquid  $\text{Cu}_2\text{S}$  were made by Kelley,<sup>6</sup> based on extrapolations from equilibrium measurements on solid  $\text{Cu}_2\text{S}$ . More recently, Cox and coworkers<sup>7</sup> studied equilibria in the reaction:

over the temperature range 700° to 1250°C. They measured equilibrium  $\text{H}_2\text{S}:\text{H}_2$  ratios presumably with both the sulphide and the metal phase present, so that their data above the melting point of  $\text{Cu}_2\text{S}$  should measure the S pressure of Cu-saturated sulphide melts. The sulphur pressures of liquid copper sulphides of several S:Cu ratios at their freezing points can be estimated from data given by Posnjak, Allen, and Merwin.<sup>8</sup> However, beyond these few data, no systematic study seems to have been made of the relations of sulphur pressure and other chemical properties of liquid copper sulphides to composition and temperature.

The measurements of the sulphur pressures of liquid copper sulphides reported in this paper represent a first step in the quantitative study of the chemistry of mattes. Similar work is planned on

Cu-Fe-S mattes and on mattes containing oxygen. The relationship of these studies to other aspects of copper-smelting chemistry was discussed in an earlier paper by one of the authors.<sup>8</sup>

The experimental work of the present investigation consisted of measurements of  $H_2S:H_2$  ratios for gas mixtures in equilibrium with liquid copper sulphides. These measurements were made for melts of varying S content, from Cu-saturation to compositions having the highest S activities conveniently determinable with  $H_2S/H_2$  mixtures. The actual composition range covered was about from 19.5 to 21.5 pct S (balance Cu) and the temperature range was from 1150° to 1350°C. In addition, equilibrium  $H_2S:H_2$  ratios were determined for systems containing the two mutually saturated phases, liquid Cu and liquid  $Cu_2S$ . From the experimental data, calculations were made of the  $S_2$  pressures and of the activities of Cu and  $Cu_2S$ . Also the data furnished a new determination of the curve showing the compositions of Cu-saturated copper sulphides in the Cu-S equilibrium diagram.

### Experimental Methods

The general procedure of equilibrium measurement was as follows: A controlled mixture of  $H_2S$  and  $H_2$  was bubbled through the Cu-S melt in a

closed furnace system. Analyses were made of the entrant and exit gases. The composition of the entrant gas mixture was adjusted until the  $H_2S:H_2$  ratios in entrant and exit gases were equal and remained equal for several hours. The final  $H_2S:H_2$  ratio thus found was considered to be the equilibrium ratio. After equilibrium was established in this way, samples of the melt were taken and analyzed chemically for S and Cu.

**Furnace Arrangement:** Fig. 1 shows the principal features of the furnace arrangement. The furnace tube was a zircon tube, 20 in. long x 3 in. in diam outside, with one end closed (test tube shape). This tube was suspended vertically in a Global furnace, with the bottom of the tube just below the thermal center of the furnace and the top projecting through the top of the furnace. The mouth of the furnace tube was closed with a brass, water-cooled head provided with openings for sealing in the various gas inlet and exit tubes and the thermocouple protection tube. This assembly was substantially gas tight at operating temperature.

The principal parts inside the furnace tube were all of high quality alumina, and the crucible, protection tubes, and gas tubes were made of pure dense alumina (Norton Co.). The space above the crucible was filled with hollow alumina pellets as insulating material. The crucible was 2x8 in. and normally contained a melt of about 250 g which filled it to a depth of about 1 in. No chemical attack or penetration of the crucible or other parts by the melt was found, and in six weeks' continuous operation at 1150° to 1350°C the only deterioration in the system was erosion of the lower end of the bubbling tube. Referring to Fig. 1, the normal path of gas flow was into the crucible through the bubbler tube and then out through the gas sampler tube. For initial flushing of the furnace tube as a whole, however, the gas was taken out through a connection in the brass head, labeled "to manometer" in Fig. 1. The normal gas flow rate into the system was 120 ml per min.

The furnace was constructed of K-30 insulating bricks in a sheet steel shell, and measured 8 in. sq x 13½ in. high inside. Eight ½-in. Globar elements furnished the heat. A Rayotube sighted through a peephole onto the zircon furnace tube was connected to a Micromax recorder-controller panel with a Leeds and Northrup position-adjusting control unit. The control unit in turn was connected to a Leeds and Northrup valve-operating mechanism mounted on a General Electric induction regulator to control automatically the power input to the furnace. With this arrangement, furnace temperatures readily were maintained constant for long periods to within about 2°C.

Melt temperatures were measured with Pt—Pt-Rh thermocouples calibrated at the gold point by the wire-bridge method. Final equilibrium temperatures were checked with two couples, each inserted in turn into the bottom of the protection tube in the melt, as shown in Fig. 1. The maximum difference between the two couples was 2°C, and most of the duplicate readings checked within 1°C.

**$H_2S/H_2$  Mixtures:** The gas mixtures fed to the furnace ranged from 0.3 to 100 pct  $H_2S$ , the balance  $H_2$ . The  $H_2S$  and  $H_2$  passed from their supply tanks through separate purification trains and flowmeters before mixing. The  $H_2$  (electrolytic) was passed over a palladium catalyst and then through calcium sul-

phate and phosphorus pentoxide drying tubes. The  $\text{H}_2\text{S}$  (Matheson, 99.9 pct) was simply dried over phosphorus pentoxide. Constant composition of the gas mixture was obtained by automatically maintaining constant pressure drops across the flowmeters, using three bubbler-type pressure regulators, one upstream of each flowmeter and one on the mixed gas downstream from both flowmeters. Sized glass powders, compacted and sintered in glass tubes, were used for flow resistances in the flowmeters. Dow-Corning 550 silicone oil was used in the manometers and pressure regulators so that the system could be dried thoroughly. The gas trains were of all glass construction, except for short connections at the supply tanks and furnace.

**Gas Analyses:** The  $\text{H}_2\text{S}/\text{H}_2$  gas mixture entering and leaving the furnace was analyzed by a method based on the fractional distillation of  $\text{H}_2$  from  $\text{H}_2\text{S}$  in vacuum at liquid nitrogen temperatures. The analytical apparatus is shown in Fig. 2. The procedure was as follows: Evacuate the bulb; collect a sample in the bulb, preferably flushing with at least 10 volumes of gas, about 1 liter, to bring the glass and stopcock grease to equilibrium with the sample; measure the pressure and temperature of the  $\text{H}_2\text{S}/\text{H}_2$  mixture; freeze the  $\text{H}_2\text{S}$  by immersing the bulb in liquid nitrogen and pump off the hydrogen, to less than 10 microns pressure; close the bulb, evaporate the  $\text{H}_2\text{S}$ , and return it to the original temperature of the gas mixture; measure the pressure of the  $\text{H}_2\text{S}$ , which is the partial pressure of the  $\text{H}_2\text{S}$  in the original gas mixture. For low percentages of  $\text{H}_2\text{S}$ , the  $\text{H}_2\text{S}$  was compressed into the smaller bulb before measuring its pressure. The ratio of the volume of the small bulb to the total volume of the two bulbs was determined by a calibration using  $\text{H}_2\text{S}$ . Corrections were made for the nonideality of the gases.

In developing this analytical method, a variety of tests were carried out. One check of the accuracy of the procedure consisted in analyzing known mixtures prepared in the bulb by admitting pure  $\text{H}_2$  and  $\text{H}_2\text{S}$  successively, measuring the pressure after each addition. Another series of tests showed that no  $\text{H}_2\text{S}$  was lost after repeated freezing with liquid nitrogen and evacuation. Table I gives the results of repeated check analysis for ten different gas compositions ranging from 0.36 to 5 pct  $\text{H}_2\text{S}$  and shows the good reproducibility obtained.

**Sampling and Analyses of Melts:** Melts were sampled using 7 mm vycor tubing with the sampling end closed to the size of a pinhole. The sampling tube was lowered into the furnace after removing the gas sampling tube. Gas was slowly drawn up through the tube to flush out air. The end was then lowered into the melt and a sample sucked into the tube. Each time 10 to 25 g were secured. For two-phase melts, the gas bubbler tube was raised and the melt allowed to settle an hour before sampling.

All samples were chemically analyzed for both copper and sulphur. The electrolytic method was used for copper. Allen and Bishop's<sup>9</sup> method, involving weighing the sulphur as barium sulphate, was used for sulphur. Difficulties were encountered in obtaining the precision desired in the sulphur determinations, so that on some samples several repeats were necessary to obtain checks. In the end, the sulphur figures obtained by duplicate chemical analyses were checked against the copper analyses (by difference) and, for sulphur contents below

Fig. 2—Gas analysis apparatus.

20.14 pct (pure  $\text{Cu}_2\text{S}$ ), were checked against analyses made by a pycnometer method.

$\text{R}_2\text{O}_3$  analyses on eight melts varied from 0.026 to 0.077 pct, averaging 0.048 pct. Iron analyses of six melts varied from 0.008 to 0.029 pct ( $\text{R}_2\text{O}_3$  includes  $\text{Fe}_2\text{O}_3$ ). These data showed the absence of melt contamination by the refractories.

**Materials:** A supply of high-purity copper was furnished by the Central Research Laboratory of the American Smelting and Refining Co. and analyzed as follows: 0.0015 pct Fe, 0.001 pct Sb, 0.0009 pct Pb, 0.0003 pct Sn, 0.0015 pct Ni, 0.00009 pct Bi, 0.001 pct As, and 0.0002 pct Te. A stock of copper sulphide was prepared by treating pieces of this copper with precipitated sulphur (U.S.P., Mallinckrodt) in a casserole heated over a laboratory burner. No precautions were taken to exclude oxygen, since any oxygen was removed as  $\text{H}_2\text{O}$  during the early stages of treatment with  $\text{H}_2\text{S}/\text{H}_2$  mixtures in the furnace. The stock copper sulphide analyzed 78.5 pct Cu.

### Experimental Results and Calculations

**Blank Runs:** Since comparison of entrant and exit gas compositions was used as the criterion of gas-melt equilibrium, it was necessary to establish the absence of side reactions in the furnace system. Accordingly, a number of runs were made passing various  $\text{H}_2\text{S}/\text{H}_2$  mixtures through the complete furnace system at temperature, but without copper sulphide in the crucible. Results of these preliminary runs may be summarized as follows:

1—A newly assembled furnace system required a break-in period of several days passing  $\text{H}_2\text{S}/\text{H}_2$  mixtures at temperature. During this period some  $\text{H}_2\text{O}$  was present in the exit gas. Also the  $\text{H}_2\text{S}:\text{H}_2$  ratio was lower in the exit gas, indicating some accumulation of sulphur in the furnace parts.

2—After the break-in period, from 8 to 24 hr operation was required to bring the furnace to equilibrium with the gas after a major change in entrant gas composition.

3—To obtain equality of entrant and exit gas compositions, all the exit gas had to be removed

Fig. 3—Log  $p_{H_2S}/p_{H_2}$  vs. mol fraction sulphur at 1150°, 1250°, and 1350°C.

from the hot zone in the crucible through the gas sampling tube, shown in Fig. 1. When part was removed this way and part through the tube in the top of the furnace, to obtain quicker flushing, thermal separation took place so that the gas removed from the hotter zone was lower in  $H_2S$  than the ingoing gas.

The preliminary runs also indirectly shed some light on the effects of the dissociation of  $H_2S$  in the furnace. Within the crucible it is to be expected that equilibrium will be established in the dissociation reaction,  $H_2S \rightleftharpoons \frac{1}{2}S_2 + H_2$ . The entering gas mixture contained only  $H_2S$  and  $H_2$ , so that the  $S_2$  must be furnished by dissociation of  $H_2S$  with a resultant change in the  $H_2S:H_2$  ratio. For this reason, the  $H_2S:H_2$  ratios measured by analysis at room temperature had to be corrected for dissociation to obtain the equilibrium values of the  $H_2S:H_2$  ratios for the furnace conditions. However, the question arises as to what happened to the gas flowing out the exit tube. The hot gas entering this tube presumably was an equilibrium mixture of  $H_2$ ,  $H_2S$ , and  $S_2$ . The absence of appreciable sulphur deposition in the colder parts of the gas exit, together with the fact that in the preliminary runs equality of  $H_2S:H_2$  ratios was obtained between entrant and exit gases, indicated that very high reaction rates were obtained so that the  $S_2$  recombined with  $H_2$  in the short time of passage of the gas through the exit tube. This behavior was essential if a comparison of entrant and exit gas analyses was to serve as the criterion of equilibrium. When the  $H_2S$  content of the entrant gas was increased to 100 pct for the final equilibrium runs on high sulphur melts, however, appreciable sulphur deposition occurred and the exit gas never reached 100 pct  $H_2S$ , although it appeared from other grounds that gas-melt equilibrium had been established in the crucible.

**Equilibrium Measurements:** In all, 32 equilibrium determinations were made, the first four in one continuous run lasting ten days and the remaining 28 in a second run lasting six weeks. Each determination involved many gas analyses and adjustments of ingoing gas composition to find the equilibrium condition. After adjustments appeared to be completed in each determination, bubbling was continued for several hours with additional gas analyses to check the existence of equilibrium before taking final samples of the melt. A number of the equilibrium gas analyses were approached from both sides. From the general behavior of the system, it appeared that gas-melt reaction was very rapid so that the rather long time spent in reaching equilibrium after a change was needed mainly to bring the furnace

\* For each run, zero time was at the end of several days' operation of the furnace at temperature with an  $H_2S/H_2$  atmosphere.

† By difference from Cu analysis, allowing 0.05 pct for impurities.

system itself, apart from the melt, to equilibrium under the new conditions.

Table II summarizes the log of the experimental work. Points 1 to 9 and 20 to 32, inclusive, represent equilibria of the gas mixtures with liquid copper sulphides of varying S content up to about 21.5 pct S. For these points the ingoing gas mixtures ranged from 0.59 up to 100 pct H<sub>2</sub>S. Except for the points at highest percentage of H<sub>2</sub>S, the entrant and exit gases were brought to equality within 0.01 to 0.02 pct H<sub>2</sub>S without difficulty. Points 10 to 19 represent equilibria of the gas mixtures with two conjugate melts, Cu and Cu<sub>2</sub>S, respectively. During these ten determinations it was observed that the exit gas after once reaching the equilibrium value remained there regardless of small variations in the gas bubbled into the melt. Thus points 10, 11, and 12 represent checks of a single equilibrium condition, the exit gas remaining at 0.506 to 0.509 pct H<sub>2</sub>S while the ingoing gas was deliberately varied from 0.527 to 0.491 pct H<sub>2</sub>S. Points 14 and 15 show a similar check. These data illustrate the rapidity of reaction of the gas with the melt obtained by the bubbling technique. For all points except 30, 31, and 32 the percentage of H<sub>2</sub>S in the outgoing gas is taken as the equilibrium value. The failure to reach 100 pct H<sub>2</sub>S in the outgoing gas for points 30, 31, and 32 was associated with sulphur deposition in cold parts of the furnace tube and gas exit tubes, so for these points it was assumed that the equilibrium gas composition was that of the products of dissociation of pure H<sub>2</sub>S at furnace temperature and pressure.

In Table III the results are placed in a more convenient form for subsequent use. The corrected

‡ Two liquid phases in equilibrium.

Fig. 4—Variation of sulphur pressure with mol fraction sulphur at 1150°, 1250°, and 1350°C.

values of  $p_{H_2S}/p_{H_2}$  were found as follows: First, the H<sub>2</sub>S:H<sub>2</sub> ratio in the outgoing gas, as found by analysis, was corrected for dissociation of H<sub>2</sub>S into H<sub>2</sub> and S<sub>2</sub> at the furnace temperature, using Kelley's free-energy equation for the dissociation reaction. Then preliminary plots of the data were made to estimate the rate of change of  $p_{H_2S}/p_{H_2}$  with temperature at the various compositions. These estimated temperature coefficients then were used to correct the values of  $p_{H_2S}/p_{H_2}$  from the odd measured temperatures to the even temperatures 1150°, 1250°, and 1350°C.

Fig. 3 shows the relations of  $\log p_{H_2S}/p_{H_2}$  to mol fraction S at 1150°, 1250°, and 1350°, and was plotted from the data in Table III. The horizontal lines at the left correspond to the H<sub>2</sub>S:H<sub>2</sub> ratio determined with both Cu and Cu<sub>2</sub>S phases present in the system, and these lines intersect the experimental curves at values of mol fraction S which represents the compositions of Cu-saturated sulphide melts. Several of the points plotted in Fig. 3 show rather larger deviations for the curves than might be desired. In this connection it should be noted that the scale of the abscissa is a rather expanded scale, the whole range from  $N_s = 0.320$  to  $N_s = 0.355$  corresponding to a range in S content of only 2.5 wt pct, from 19.2 to 21.7 pct S. This composition range is considerably smaller than was anticipated from previous work.<sup>3</sup> Accordingly, the scatter in Fig. 3 results chiefly from small errors in the melt analyses. In drawing the smooth curves in the vicinity of the Cu<sub>2</sub>S composition, the following matters were considered: 1—The solid solubility of Cu in Cu<sub>2</sub>S is small, so that the presence or absence of metallic Cu in the solid samples (determined by microscopic examination) was used as a supplementary guide in checking the analyses of samples near Cu<sub>2</sub>S in composition.<sup>4</sup> 2—The curves probably should not inflect at the composition Cu<sub>2</sub>S. 3—If the curves intersect at all, all three should do so at a common point to avoid the improbable finding that the partial molal heat of solution of S in the melt varies sharply with temperature.

Fig. 4 shows the relations of  $p_{S_2}$  to composition for the three experimental temperatures. These curves were calculated to correspond to the smoothed curves of Fig. 3, using Kelley's<sup>6</sup> free-energy equation for the dissociation of  $H_2S$  to calculate equilibrium values of  $p_{S_2}$  corresponding to the measured values of  $p_{H_2S}/p_{H_2}$ . Kelley's data for this equilibrium are represented accurately in the temperature range of this investigation by the relation:

$$\log p_{S_2} = 2 \log \left( \frac{p_{H_2S}}{p_{H_2}} \right) - \frac{9665}{T} + 5.342$$

The plot in Fig. 4 shows the very steep variation of sulphur pressure with composition,  $p_{S_2}$  increasing from the vicinity of  $10^{-6}$  and  $10^{-5}$  atm for liquids below  $Cu_2S$  in sulphur content to nearly 1 atm for liquids containing a small excess of S over  $Cu_2S$ .

In view of the steep variation of sulphur pressure with sulphur content and in view of the accompanying experimental uncertainties in sulphur analyses, the data do not permit accurate determinations of the heat of solution of sulphur in the melts from the variation of sulphur activity with temperature at constant composition. However, on the basis of the smoothed data as represented by the curves in Fig. 3, the partial molal heat content of sulphur in the melt relative to  $H_2S$  gas increases from about -28,000 cal per g-atom S in Cu-saturated melts to about -12,000 cal for  $Cu_2S$  and then increases further to about +12,000 cal for the highest S melts. The corresponding estimates for the differential heat of solution of  $S_2$  gas in the melts are -100,000 cal per g mol  $S_2$  in Cu-saturated melts, -68,000 cal per g mol in  $Cu_2S$ , and -20,000 cal per g mol in the melts having sulphur pressures approaching an atmosphere (21.5 pct S).

**Sulphur Activities and Compositions of Cu-Saturated Liquids:** Fig. 5 shows the relationship of log

$$\frac{p_{H_2S}}{p_{H_2}} \text{ to } \frac{10^4}{T} \text{ for equilibrium determinations 10}$$

through 19 in which two liquid phases,  $Cu_2S$  and Cu, were present at equilibrium in the crucible. The experimental points fall on a straight line within experimental error, following the relation:

$$\log \frac{H_2S}{H_2} = -\frac{2920}{T} - 0.394$$

Also plotted in Fig. 5 are the data of Cox and co-

Fig. 5—Relation of  $\log p_{H_2S}/p_{H_2}$  to  $1/T$  for Cu-saturated melts.

Fig. 6—Activities of Cu and  $Cu_2S$  calculated by Gibbs-Duhem integration.

workers,<sup>7</sup> which check the new data reasonably well. Combination of the above equation with the rela-

tion of  $p_{S_2}$  to  $\frac{p_{H_2S}}{p_{H_2}}$  and  $T$  derived from Kelley's data

gives the relation of  $p_{S_2}$  to  $T$  for Cu-saturated melts:

$$\log p_{S_2} = -\frac{15,505}{T} + 4.56$$

The mol fractions of S ( $N_s$ ) corresponding to Cu saturation can be read from Fig. 3 at the intersections of the horizontal lines giving  $\log \frac{p_{H_2S}}{p_{H_2}}$  for the systems containing two liquid phases with the curves for sulphide melts of varying composition. Table IV gives the results of these determinations and includes also the recent determination by Jensen<sup>4</sup> at 1105°C, which checks well with the results of the present investigation. As mentioned previously, the various determinations of the compositions of Cu-saturated mattes reported in the literature have been somewhat discordant, some of the earlier work indicating a composition range from Cu-saturation to  $Cu_2S$  as much as five times the range in percent S (e.g., 19.4 to 20.14 pct S at 1350°C) found in the present investigation. When the various experimental methods are considered, the authors feel that the data in Table IV represent the most reliable information on the compositions of Cu-saturated sulphide melts.

**Activities of Cu and  $Cu_2S$ :** Using the Gibbs-Duhem integration,<sup>10</sup> copper activities can be calculated from the relationship of sulphur activity (measured by  $p_{H_2S}/p_{H_2}$ ) to mol fraction S ( $N_s$ ). That is, at constant temperature:

$$\log a_{Cu} = -\int \frac{N_s}{1-N_s} d \log \frac{H_2S}{H_2}$$

In evaluating this integral, it is necessary to select as a limit the standard state for copper in which  $a_{Cu} = 1$ . It would be desirable to use pure liquid Cu as the standard state, but the data are not yet available to carry the above integration to this limit on the liquid-Cu side of the Cu-S system. Accordingly, the standard state for copper was arbitrarily chosen as the solution of composition corresponding exactly to  $Cu_2S$ , for which  $N_s = 1/3$ . Results of the integration based on the experimental data are plotted in Fig. 6. It can be seen that the activity of

Cu in liquid  $\text{Cu}_2\text{S}$  is roughly half the activity of Cu in a liquid-Cu-saturated melt, and, therefore, is a little less than half the activity of pure liquid Cu. In general, also, the activity of copper decreases rather sharply with increasing sulphur content, as would be expected from the rapid increase in sulphur pressure.

The gas-melt equilibria can be considered in terms of the reaction:

for which the equilibrium constant is:

$$k = \frac{p_{\text{H}_2\text{S}} a_{\text{Cu}}^2}{p_{\text{H}_2} a_{\text{Cu}_2\text{S}}}$$

If the standard states for both Cu and  $\text{Cu}_2\text{S}$  are taken as the solution of composition  $\text{Cu}_2\text{S}$ , the equilibrium constant at any temperature becomes equal to  $p_{\text{H}_2\text{S}}/p_{\text{H}_2}$  at the composition  $\text{Cu}_2\text{S}$  and can be evaluated from the experimental data, giving:

$$\log k = -\frac{2630}{T} + 0.059$$

The corresponding equation for the standard free-energy change in the reaction is:

$$\Delta F^\circ = 12,000 - 0.27T$$

It should be kept in mind that this free-energy equation is valid only for the standard states of Cu

Table IV. Compositions of Cu-Saturated Copper Sulphide

| Temperature, °C | Mol Fraction S | S, Wt Pct | $\text{Cu}_2\text{S}$ , Wt Pct |

\* From Jensen.<sup>4</sup>

and  $\text{Cu}_2\text{S}$  for which the equation is derived and thus should not be compared directly with other free-energy equations for the same reaction but based on different standard states.

Activities of  $\text{Cu}_2\text{S}$  for various compositions of liquid sulphides at various temperatures can be calculated by substituting  $p_{\text{H}_2\text{S}}/p_{\text{H}_2}$  and  $a_{\text{Cu}}$  (from the Duhem integration) into the equilibrium constant and then solving for  $a_{\text{Cu}_2\text{S}}$ . Results of these calculations are plotted in Fig. 6. One curve shows the results of the calculations adequately over the entire temperature range 1150° to 1350°C of the present investigation.

### Summary

The activity of sulphur in liquid copper sulphide, from compositions corresponding to saturation with copper to compositions approaching 1 atm in sulphur pressure, was measured over the temperature range 1150° to 1350°C. The experiments consisted in finding for each melt composition and temperature the ratio  $p_{\text{H}_2\text{S}}/p_{\text{H}_2}$  in a gas mixture at equilibrium with the melt. Equilibrium was established by bubbling the gas mixture through the liquid and adjusting the gas composition until no reaction occurred, as shown by comparison of the  $p_{\text{H}_2\text{S}}/p_{\text{H}_2}$  ratio in entrant and exit gases. The equilibrium partial pressures of  $\text{S}_2$  gas were calculated from the  $p_{\text{H}_2\text{S}}/p_{\text{H}_2}$  data, using Kelley's free-energy equation for the dissociation of  $\text{H}_2\text{S}$ .

The sulphur pressures ( $p_{\text{S}_2}$ ) of liquid copper sulphides were found to be very sensitive to composition, especially as the S contents were increased beyond  $\text{Cu}_2\text{S}$ . At 1150°C,  $p_{\text{S}_2}$  was found to be  $4.6 \times 10^{-7}$  atm for Cu-saturated melt,  $9.4 \times 10^{-6}$  atm for  $\text{Cu}_2\text{S}$  (20.14 pct S), and 0.14 atm for the 21.5 pct S melt. The corresponding figures at 1250°C were  $2.4 \times 10^{-6}$ ,  $4.6 \times 10^{-5}$ , and 0.23 atm, respectively, and at 1350°C were  $10^{-5}$ ,  $1.8 \times 10^{-4}$ , and 0.35 atm, respectively. The large increase in  $p_{\text{S}_2}$  for slight increases in S above  $\text{Cu}_2\text{S}$  accounts for the well-known fact that artificial preparations of  $\text{Cu}_2\text{S}$  involving melting in open containers always give products close to  $\text{Cu}_2\text{S}$  in composition.

The sulphur pressures ( $p_{\text{S}_2}$ ) of liquid copper sulphides increase with increasing temperature, this increase being more marked for liquids below  $\text{Cu}_2\text{S}$  in sulphur content. From the variations of  $p_{\text{S}_2}$  with temperature, the partial molal heats of solution of  $\text{S}_2$  were estimated to be approximately -100,000 cal per mol for Cu-saturated melts, -68,000 cal per mol for  $\text{Cu}_2\text{S}$  (20.14 pct S), and -20,000 cal per mol for melts with 21.5 pct S.

The equilibrium measurements for the systems containing the two conjugate solutions, liquid Cu and liquid  $\text{Cu}_2\text{S}$ , are represented by the following equation:

$$\log \frac{p_{\text{H}_2\text{S}}}{p_{\text{H}_2}} = -\frac{2920}{T} - 0.394$$

The corresponding equation for the sulphur pressure of the two-phase system is as follows:

$$\log p_{\text{S}_2} = -\frac{15,505}{T} + 4.56$$

The sulphur contents of the liquid copper sulphides saturated with copper were found to be 19.8 pct at 1150°C, 19.6 pct at 1250°C, and 19.4 pct at 1350°C. These results are concordant with Jensen's recent determination of 19.79 pct at 1105°C but disagree with earlier data which indicated a much larger solubility of Cu in  $\text{Cu}_2\text{S}$ .

# Microscopic Observation of the Solidification Of Cu-Ni Alloy Droplets

by R. E. Cech and D. Turnbull

THE supercooling behavior of pure liquid metal droplets has been described.<sup>1</sup> The solidification behavior of small droplets of Cu-Ni alloys as a function of composition is described herein. The Cu-Ni system is of interest for such an investigation because the components are miscible in all proportions in both the liquid and solid state and the phase diagram of the system, Fig. 1, is a type often encountered in metal systems.

It was noted by Van Riemsdyk<sup>2</sup> and others that the nature of the "blick" of gold droplets during assaying is not perceptibly affected by the content of the platinum group metals that are soluble in both liquid and solid gold. With the exception of these very qualitative observations there appear to have been no prior investigations of the supercooling of alloy droplets.

A series of nine alloys varying in composition by 10 pct (nominal weight) steps was made using certified OFHC copper, 99.996 pct purity, obtained from the American Brass Co., and electrolytic nickel pellets, 99.92 pct purity, obtained from the International Nickel Co. The alloys were melted and cast in vacuo in a high frequency induction furnace. Segregation was minimized by chill casting into 1-in. diam steel molds. Each alloy rod was homogenized at a temperature 50°C lower than the solidus for 100 hr in dry hydrogen. Samples for solidification experiments and chemical analysis were machined from the same portion of each rod and at a depth of 1/4 in. from the rod surface. A Carboloy tool was used in taking turnings to minimize contamination of sample by the cutting tool. As a

check, a number of samples for microscopic observation were chipped from the ingot with a fragment of pyrex glass. The resultant data in all cases agreed, within experimental error, with the data obtained from machined turnings.

A number of small particles, 30 to 50 micron diam, of a Cu-Ni alloy were placed in a quartz vial 1/32 in. diam x 1/4 in. long. This was inserted into a platinum ribbon heater and mounted in a high temperature microscope stage. The general procedure followed in inserting samples into the stage and measuring the temperature of melting and solidification was the same as described in an earlier paper.<sup>1</sup> A chromel-alumel thermocouple was used to study alloys of 88.93 pct Cu, 80.62 pct Cu, and 72.27 pct Cu. A platinum-10 pct rhodium thermocouple was used for the remainder of the alloys.

## Procedure

The assembled high temperature microscope stage was first evacuated and the sample given a 2 min in situ treatment at 900°C in dry hydrogen to remove surface oxides which might otherwise catalyze crystal nucleation. After this treatment the atmosphere was changed to purified helium and melting and solidification were observed microscopically. It was not possible to determine the solidus with certainty. However, the liquidus temperature was measured very accurately since the surface of the particle changed in appearance from coarse and uneven to smooth, mirror-like within a few degrees. The visually determined liquidus temperature was checked by finding the highest temperature to which the particle could be heated such that it did not supercool upon lowering the temperature. This temperature which checked within experimental error with that found by observing surface change was assumed to be characteristic of the thermodynamic liquidus. In order to minimize the effect of selective evaporation of copper from the alloy, samples were changed frequently and the droplets were heated no more than 50°C in excess of the liquidus temperature  $T_1$ . When the latter conditions were fulfilled,  $T_1$  values were reproducible.

After melting, the temperature was decreased slowly until the particles solidified. The sudden release of heat of fusion on solidification caused the

Fig. 1—Solidification temperatures of Cu-Ni alloys as a function of composition.

supercooled particles to blink, or recalesce. Also, at the same instant, the particle surface could be observed to change from mirror-like to a dendritic type pattern. It was necessary, when observing the higher melting, Ni-rich alloys to use filters to decrease radiation intensity.

## Results

The alloy compositions and results are summarized in Table I and plotted on the constitution diagram of Fig. 1. The  $(\Delta T_-)_{\max}$  values listed for pure copper and nickel were taken from the previous investigation of pure metals.<sup>1</sup> The values of  $(\Delta T_-)_{\max}$  for the alloys are the average of several determinations on a number of samples but the maximum deviation observed in any determination was within 2 pct of the average.

In agreement with earlier observations on pure metals the frequency of supercooling to  $(\Delta T_-)_{\max}$  was much less in the absence of a flux. It is probable that the pyrex flux combined with nucleation catalysts that may have been picked up from the alundum crucibles used in making the alloys. When a pyrex flux was used the particles supercooled to  $(\Delta T_-)_{\max}$  consistently.

Occasionally, a surface oxide coating that nucleated solidification at  $\Delta T_- < (\Delta T_-)_{\max}$  formed on the alloys of 88.93 pct Cu and 80.62 pct Cu in a helium atmosphere. Therefore, a hydrogen atmosphere was used for these alloys. The ratio  $\Delta T_{-\max}/T_1$  for results obtained in hydrogen agree very well with the ratios for the other alloys of the system.

The metal droplets after solidification displayed a dendritic surface structure. A micrograph of a supercooled droplet of 80.62 pct Cu in cross-section (Fig. 2) illustrates the dendritic structure formed during solidification. It was also apparent that the solidified particle was a single crystal as might be expected in view of the rapid crystal growth rate. The dendritic segregation may indicate that at least a portion of the droplet had been heated to the equilibrium freezing temperature before solidifying. Neglecting heat losses to the surroundings, the latent heat of fusion released by the solidification of approximately 60 pct of the droplet is sufficient to heat the entire droplet to the equilibrium temperature. It is therefore apparent that segregation during solidification may occur in a supercooled alloy droplet as well as in bulk solidification.

The initial solidification temperatures are more properly defined as temperatures at which the frequency of nucleus formation becomes very great. It is known that the temperature dependence of nucleation rates in tin<sup>4</sup> and mercury<sup>5</sup> is so great that

Fig. 2—Cross-section of 80.62 pct Cu alloy droplet supercooled to  $\Delta T_{-\max}$  before solidification. X500.

even large variations in speed of cooling will have no perceptible effect, in these experiments, on the temperature of initial solidification. To extend the knowledge of temperature dependence of nucleation rate to alloys in a qualitative way, a number of 50 micron particles of 40.89 pct Cu were first melted and then cooled to a temperature 20°C above  $(\Delta T_-)_{\max}$  and held 30 min. Upon further cooling they were found to solidify at  $(\Delta T_-)_{\max}$  thus indicating that the prolonged hold at the higher temperature had no measurable effect on the temperature of subsequent solidification.

## Summary

The solidification behavior of Cu-Ni alloy droplets was studied as a function of composition by means of a high temperature microscopic technique described previously.<sup>1</sup> The ratio of the amount of supercooling  $(\Delta T_-)_{\max}$  to the absolute liquidus temperature was found to be  $0.18 \pm 0.01$ , see Table I, which checks closely the value of  $0.18 \pm 0.02$  for the ratio of  $(\Delta T_-)_{\max}$  to the absolute melting temperature found for pure metals.

A cross-section of a supercooled particle displayed segregation indicating that the heat of fusion was probably sufficient to raise the droplet to the equilibrium freezing temperature and allow a portion of the particle to solidify by normal dendritic growth.

It was demonstrated that the temperature dependence of the nucleation rate was about as large as for pure metals.

# Solubility of Hydrogen in Molten Lead

by W. R. Opie and N. J. Grant

THE amount of hydrogen that will dissolve in lead has been considered negligible. However, a limited number of measurements made recently using apparatus built for determining hydrogen solubility in aluminum alloys<sup>1</sup> indicate that liquid lead will hold a small but appreciable amount of hydrogen in solution. The apparatus used was similar to that developed by Sieverts.<sup>2</sup> This consists of a bulb to hold the molten metal, a gas burette for introducing a measured quantity of gas into the bulb and a manometer for measuring the gas pressure in the bulb. Measurements are made by introducing enough of an insoluble gas (helium) to fill the system at a given temperature and pressure, thereby determining the hot volume of the bulb. This gas then is pumped out and hydrogen is introduced until the same pressure is reached, the metal being maintained at the same temperature while in contact with each gas. The difference between the volumes corrected for pressure is then the hydrogen solubility. A more detailed account of the procedure can be found in refs. 1 and 2.

The lead was melted in an alundum crucible by induction heating to provide uniform temperature and an important stirring effect. The metal was the purest obtainable, 99.999+, prepared especially by the research department of the American Smelting

Fig. 1—Effect of temperature upon the solubility of hydrogen in molten lead at 760 mm Hg.

Fig. 2—Effect of pressure upon the solubility of hydrogen in molten lead.

and Refining Co. Measurements were made by approaching the equilibrium value from high and low temperatures during the constant pressure runs, and from high and low pressures when the temperature was held constant. Thus a number of measurements were made on each of two large samples which weighed 336 and 398 g. The gases were purified as described in ref. 1.

The effect of temperature on the solubility was studied with the pressure held constant at 760 mm of Hg. To show the effect of pressure, solubility measurements were taken at two constant temperatures, 600° and 900°C.

## Results

The effect of temperature on hydrogen solubility is shown in Fig. 1. The curve representing the data is parabolic, as are plots of hydrogen solubility vs. temperature for other metals and alloys (aluminum,<sup>1</sup> copper,<sup>3</sup> and iron,<sup>4</sup> for example). Fig. 2 shows the relationship that exists when the solubility is

W. R. OPIE, Junior Member AIME, is Research Metallurgist, Titanium Div., National Lead Co., Fords, N. J.; and N. J. GRANT, Member AIME, is Associate Professor, Department of Metallurgy, Massachusetts Institute of Technology, Cambridge.

Discussion of this paper, TP 3037E, may be sent to AIME by May 1, 1951. Manuscript, Oct. 2, 1950. St. Louis Meeting, February 1951.

plotted against the square root of the pressure. As can be seen from this plot, the Sieverts' relationship, "solubility of a diatomic gas varies as the square root of the pressure if the temperature remains constant," can be applied to lead. The fact that the lines relating the solubility to the square root of the pressure do not quite pass through the origin indicates that the values are slightly low. This can be explained primarily by the difference in heat conductivity between hydrogen and helium but also by the small values of solubility being measured. Hydrogen, being a better conductor than helium, would heat the surrounding bulb glassware above the metal to a slightly higher temperature than would the helium. Because the space in the system occupied by the gas is hotter when hydrogen is in contact with the metal, the net result is that less hydrogen than helium for a given pressure is needed to fill this space. This effect is very much more pronounced when a gas with even lower heat conductivity, such as argon, is used as the inert gas, as was observed in several trial runs.

When the equilibrium constant  $\log_{10}$  for the solubility equation:

determined by expressing the solubility as the mol fraction, is plotted against the reciprocal of the absolute temperature, the heat of solution can be calculated from the slope of the line using the Van't Hoff equation:

$$\log_{10} K = \frac{-\Delta H}{0.575 T} + C$$

Fig. 3 is such a plot with the solubility, ( $\log_{10}$ ) expressed in cc of hydrogen per 100 g of lead, and the equilibrium constant ( $\log_{10}$ ) both plotted against the reciprocal absolute temperature. From this plot the solubility may be expressed as:

$$\log_{10} S = \frac{-2450}{T} + 2.19$$

The total heat of solution, including the heat of dissociation of diatomic to monatomic hydrogen and the heat of solution of the monatomic hydrogen, has

Fig. 3—Van't Hoff plot of solubility data.

been determined from the slope to be 22,300 cal per mol of diatomic hydrogen.

### Conclusions

1—The solubility of hydrogen in molten lead may be expressed by the equation:

$$\log_{10} S = \frac{-2450}{T} + 2.19$$

2—Sieverts' law is obeyed within the temperature and pressure ranges investigated.

3—The heat of solution of hydrogen in lead is 22,300 cal per mol of diatomic hydrogen.

### Technical Note

## Surface Diffusion in Sintering of Spheres on Planes

by P. Schwed

IN determining the mechanism responsible for sintering, the most direct procedure available is the comparison of the observed time and temperature dependence of the process with the dependence to be expected upon the basis of each conceivable mechanism. This was done by Kuczynski<sup>1</sup> who, in treating the mechanism of surface diffusion, postulated, in effect, that the concentration gradient of vacancies is different from zero only within the

neck. This procedure was recently questioned by Cabrera<sup>2</sup> who assumed, on the contrary, that diffusion occurs only in the region outside the neck. In the present note, the calculations are performed without restriction on the region of diffusion.

To carry out this objective it is first necessary to

P. SCHWED is associated with National Advisory Committee for Aeronautics, Lewis Flight Propulsion Laboratory, Cleveland.  
TN 68E. Manuscript, Dec. 14, 1950.

review briefly Cabrera's approach. He divided the surface of the sphere being sintered into two parts: 1—A flat portion,  $AB$  in Fig. 1, with an essentially infinite radius of curvature; and 2—the neck,  $AA$  in Fig. 1, which at a given stage of the process has a radius of curvature,  $\rho$ . This difference in curvature leads to a higher concentration of vacancies in the neck with the result that diffusion of atoms occurs into the neck from the undisturbed part of the surface. It is assumed further that there exists a process, say condensation, which replaces the atoms lost from the flat part of the surface; and the equation of continuity is solved for this region of the surface under the assumption that diffusion and condensation balance (time independence) and with the boundary condition that the concentration of atoms at the junction,  $A$ , between the neck and the flat surface is that appropriate to the neck. The current at the junction then is calculated, and from the current the law of growth of the neck may be found.

This approach suffers from the difficulty that the equation of continuity does not hold throughout the surface, since the current of atoms is discontinuous across the boundary. This follows from the fact that the concentration of atoms in the neck is taken as constant so that the current of atoms within the neck is everywhere zero, according to the diffusion equation. The inconsistency here arises from a failure to consider in proper detail the situation at the surface of the neck. The most direct way of doing this is to apply the same principles to calculating the concentration in the neck as were employed for the flat surface. This means that the process which supplies the atoms lost by the flat region removes the excess atoms in the neck, for instance by evaporation.

Revising Cabrera's notation slightly, let  $n_1$  be the concentration of adsorbed atoms in the flat region and  $n_2$ , that in the neck; further, let  $y$  be a coordinate measured from the junction  $A$  with a positive direction away from the neck and  $y_s = (D_s t_s)^{1/2}$  where  $D_s$  is the coefficient of surface diffusion and  $t_s$  is the relaxation time for condensation. Then, if  $n(\infty)$  and  $n(\rho)$  are the equilibrium concentrations of adsorbed atoms in the flat surface and neck, respectively, the appropriate equations are (cf. ref. 2, eq 3):

$$\frac{d^2}{dy^2} [n(\infty) - n_1] = \frac{n(\infty) - n_1}{y_s^2} \quad [1]$$

and

$$\frac{d^2}{dy^2} [n(\rho) - n_2] = \frac{n(\rho) - n_2}{y_s^2} \quad [2]$$

Eq 2 is based upon the assumption that diffusion occurs along the curved surface of the neck in essentially the same fashion as on a plane surface of the same length. The following boundary conditions apply:

$$\begin{aligned} n_1 &= 0 \text{ at } y = \infty \\ n_1 &= n_2 \text{ at } y = 0 \end{aligned}$$

$$\frac{dn_1}{dy} = \frac{dn_2}{dy} \text{ at } y = 0 \quad [3]$$

$$\frac{dn_2}{dy} = 0 \text{ at } y = y_0 = -\frac{\pi\rho}{2} \text{ (center of neck)}$$

where  $y_0$  is the coordinate of the center of the neck.

The last two follow respectively from the equality of currents at the junction  $A$  and the vanishing of the current at the center  $C$ , of the neck on account

Fig. 1—Typical sphere.

of symmetry. The solution of eqs 1 and 2 subject to the conditions of eq 3 is:

$$\begin{aligned} n(\infty) - n_1 &= \frac{n(\infty) - n(\rho)}{2} (1 - e^{\frac{2y_0}{y_s}}) e^{-\frac{y}{y_s}} \\ n(\rho) - n_2 &= \left[ \frac{n(\infty) - n(\rho)}{2} \right] (e^{\frac{y}{y_s}} + e^{-\frac{y+2y_0}{y_s}}) \end{aligned} \quad [4]$$

The current  $J_s$  through the junction  $A$  is therefore:

$$\begin{aligned} J_s &= \frac{n(\infty) - n(\rho)}{2} \frac{D_s}{y_s} (1 - e^{\frac{2y_0}{y_s}}) \\ &= \frac{n(\infty) - n(\rho)}{2} \frac{D_s}{y_s} (1 - e^{-\frac{\pi\rho}{y_s}}) \end{aligned} \quad [5]$$

In interpreting eq 5, it is necessary to exercise caution. If the process balancing diffusion is literally condensation or evaporation, the current found leads to no net growth since the atoms entering the neck are evaporated forthwith. If, however, the alternative suggestion of Cabrera's is followed, that the interchanges implied are between atoms in the kinks on the surface and normal surface atoms, the observed build-up of the surface of the neck occurs since the atoms entering the neck remain there. Assuming the latter process to be correct, eq 5 may be used to find the rate of sintering. For

$$\rho \ll \frac{y_s}{\pi}, 1 - e^{-\frac{\pi\rho}{y_s}} \text{ is nearly equal to } \frac{\pi\rho}{y_s}, \text{ and,}$$

because  $n(\infty) - n(\rho)$  varies as  $\frac{1}{\rho}$ ,  $J_s$ , as given by eq 5, is independent of  $\rho$  and the law of growth of the neck is  $x^3 \sim At$  where  $2x$  is the neck diameter.

On the other hand, for  $\rho \gg \frac{y_s}{\pi}$ , the law of growth is  $x^5 \sim At$  and is the same as for volume diffusion. It follows that on the present theory it is possible to distinguish surface diffusion from volume diffusion by experiments on small particles.

To expedite comparison of the three calculations a brief table giving the results of each of these is as follows:

|                        | $\rho \ll \frac{y_s}{\pi}$ | $\rho \gg \frac{y_s}{\pi}$ |
|------------------------|----------------------------|----------------------------|
| Kuczynski <sup>1</sup> | $x^3 \sim At$              | $x^3 \sim At$              |
| Cabrera <sup>2</sup>   | $x^5 \sim At$              | $x^5 \sim At$              |
| Eq 5                   | $x^3 \sim At$              | $x^5 \sim At$              |

# Re-solution of Precipitated Silver in Copper-Silver Alloys

by Harold Margolin and Walter R. Hibbard, Jr.

**D**URING preliminary tests on the aging of a Cu-plus 5 pct Ag alloy,<sup>1</sup> a specimen which had been overaged 24 hr at 550°C was annealed in a nitrogen-hydrogen atmosphere first for 2 hr and then for an additional 28 hr at 600°C. After each anneal the specimen was cooled to room temperature in about ½ hr and X-ray photograms were made. The first film, Fig. 1a, revealed two sets of copper-base lines, one intense and corresponding to the parameter at 550°C, the other fainter and shifted away from the beam, corresponding to the larger parameter at 600°C (see arrows). The 30-hr film, Fig. 1b, revealed the same two sets of copper-base lines with a reversal of intensity. In neither case do the copper lines form a broad band which would be indicative of a range of compositions. This phenomenon is thus a "discontinuous" type of solution. A similar phenomenon was observed in a Ag-rich Cu-Ag alloy.<sup>2</sup> Finlay and Hibbard<sup>3</sup> have suggested that directional rather than random solution of precipitate occurs in some alloys.

Conceivably, for Cu-Ag alloys, the matrix-transition-precipitate precipitation sequence is reversible for the re-solution of the precipitate caused by rapidly raising the annealing temperature of an overaged specimen. A copper-base transition structure supersaturated with solute might be formed around the precipitate as it dissolves, thus obviating the necessity for a gradually changing solute composition of the matrix. The solute atoms then might be transferred rapidly and locally from the transition to the matrix phase in the proper amount and at the proper location to obtain directly the new ex-

Fig. 1a (top)—Cu-Ag alloy aged 24 hr at 550°C, annealed 2 hr at 600°C.

Fig. 1b (bottom)—Same as Fig. 1a, but annealed 30 hr at 600°C.

panded solid solution. The theory implies a minimum of diffusion of solute in the matrix (i.e., no significant range of matrix composition) and possibly suggests that the composition of the transition structure will vary with the conditions of re-solution. A transition copper phase found in aged Cu-Ag alloys<sup>1</sup> might fulfill this function.

Evidence regarding this suggestion could be obtained in Cu-Ag alloys by overaging a specimen until no trace of the expanded copper lattice is present and then subjecting the specimen to a retrogression treatment. Re-appearance of the transition copper phase would confirm the theory. Additional details could be secured by varying both aging and retrogression temperatures.

# Fractographic Pattern for 475°C Embrittlement in Stainless Steel

by Carl A. Zapffe

**F**OR a number of years a puzzling phenomenon of brittleness in Class II ferritic stainless steels, developing in the temperature range near 475°C, has received increasing attention, but its nature remains essentially unknown. During an investigation of the fractographic structures in stainless steels, conducted in the author's laboratory the past several years, principally under sponsorship of the Office of

Naval Research, some observations of a new kind were found for "475°C embrittlement."

While the details of the study cannot be given here,<sup>1</sup> three fractographs will suffice to carry the

Fig. 1a (top)—Fractographic pattern for Type 446 stainless steel produced by rifle fire at 100°C, showing transgranular fracture typical for both embrittled and unembrittled metal at temperatures below the fractological change.

Fig. 1b (center)—Specimen fractured by rifle fire at 475°C. Still transgranular, the pattern expresses the fractological change, the crystallographic markings now representing slip rather than intersecting cleavages.

Fig. 1c (bottom)—Fractographic pattern believed to reveal a grain boundary precipitate and the phenomenon responsible for 475°C embrittlement.

Figs. 1a-1c: X850. Area reduced approximately 75 pct for reproduction.

point. These concern a sample of Type 446 stainless steel, held at 1150°C for 2½ hr, and slowly cooled in the furnace both to grow large grains and to expose the material to 475°C embrittlement as it passed through that range. Numerous other tests were conducted also, including some in which the specimens were held for 200 hr at temperatures within the embrittling range, but the results of all tests were similar.

In Fig. 1a a fractograph is shown for this steel fractured at 100°C by rifle fire from a 0.22-caliber bullet at a distance of 24 in. from the muzzle. The specimen was ¼-in. round bar containing a rectangular notch. The pattern discloses a sharp rec-

tangular symmetry of transgranular cleavage traverse on (001). Intersecting {100} cleavages are clearly evident. All visible angular relationships lie primarily at 90°, also at 45°.

This pattern is typical for *transgranular fracture* through this grade of steel whether fractured by hammer blow or by rifle fire over a wide range of temperature, and whether the metal has been embrittled or not by the phenomenon under discussion. No observable change in transgranular fracture pattern was caused by 475° embrittlement.

At temperatures above approximately 100°C, a fractological change manifests itself for specimens broken by hammer blow,<sup>2</sup> elastic responses being preceded by important plastic deformation with consequent obscuration of the fractographic pattern. By means of the higher velocity of rifle fire, the temperature of this fractological change is shifted upwards, such that a certain proportion of observable transgranular facets persists even at 475°C. One of these is shown in Fig. 1b. It will be noted that the pattern remains relatively flat, but that few if any of the block-like markings are in evidence. The parallel traces in this figure are believed to be slip markings, probably on {110}.

Although fracture in embrittled steel is predominantly transgranular, as just shown, an occasional facet is found such as that in Fig. 1c. There the completely altered texture resembles nothing so far found in specimens free from embrittlement. The study of a number of these patterns is convincing that they represent surfaces of individual grains, and that a superficial phase forming along the grain boundaries is directly associated with 475° embrittlement. While at first it seems strange that a grain boundary phase should promote transgranular elasticity, exactly that relationship generally has been agreed upon by previous investigators.

No steps have been taken for direct analysis of this superficial coating; but its general appearance carries a strong similarity with an intergranular coating in cast molybdenum known to be molybdenum oxide.<sup>3</sup> A possibility then presents itself to hypothesize that the phenomenon of 475° embrittlement involves a *chromium oxide*, rather than an intermetallic combination of Fe and Cr.

Further, it is proposed that some attention be paid the protoxide CrO as a possible factor: Chromium monoxide has been identified in several research fields as a prominent constituent of chromiferous steels,<sup>4</sup> and one which deserves further attention by metallurgists. The protoxide is particularly significant because it represents the oxide phase having a direct relationship with oxygen dissolved in the metal—such as FeO in the Fe-O system. Thus it can precipitate and redissolve in crossing its saturation boundary, much in conformity with known effects of thermal treatments on 475° embrittlement.

## Structure of Spherulites in Nodular Cast Iron

by H. E. Stauss, F. W. Von Batchelder, and E. I. Salkovitz

**E**XISTING information regarding the structure of a spherulite in nodular cast iron is based on optical studies. According to these data, a nodule consists of an aggregate of graphite crystallites radiating from the center, with the closely packed basal planes at right angles to the radii. The  $c$  axes lie along the radii. This view faces some uncertainty in the fact that the  $c$  axis does not represent the accepted direction of fastest growth in graphite.

To supplement the optical information, X-ray studies have now been made. The principle used was to screen the nodule in greater part from the X-ray beam and expose only a minor cap. As successively larger portions of the nodule were introduced into the X-ray beam, any differences in the X-ray patterns could be observed. Such photographs have been taken with chromium radiation and a Laue camera. The graphite nodule itself, about 0.010 to 0.025 in. in diam, was mounted with vaseline on a micrometer screw for control of the linear motion. The nodule rotated about  $45^\circ$  each time that it was translated linearly. The nodules were obtained from magnesium-treated hypereutectic iron by electrolytic solution of the iron in hydrochloric acid.

In Fig. 1a is shown the pattern of the thinnest cap examined. In Fig. 1b is shown the pattern of the same nodule moved 0.003 in. farther into the X-ray beam, and rotated  $45^\circ$  at the same time. Figs. 1a and 1b indicate incomplete circles for graphite (the two outer circles arise from graphite) with the side arcs much weaker than the top and bottom ones. The arcs obtained are themselves not continuous in intensity but vary with maxima of intensity some  $15^\circ$  and  $30^\circ$  apart.

The structure of the nodule that would give rise to such a pattern can be explained as follows. Basically the nodule consisted of small crystallites. The discontinuous character of the diffraction rings demonstrates that the nodule was not composed of randomly oriented crystallites. The strong vertical reflections and the weak lateral reflections show that the reflecting planes were roughly normal to the radii. The absence of sharp reflection spots suggests that the nodule did not contain large crystals. The sharpness of the diffraction rings in their radial direction shows that the variations in intensity along the arcs were not the result of line broadening resulting from extremely small crystals. In the diffraction patterns two rings corresponding to graphite were found. The third and inner ring in the figures originated in the vaseline. The graphite rings correspond to the  $\alpha$  and  $\beta$  lines reflected from the basal planes, showing that the radii of the

Fig. 1a (top)—Laue pattern of thinnest cap of graphite spherulite from magnesium inoculated hypereutectic iron.

Fig. 1b (bottom)—Laue pattern of spherulite moved 0.003 in. farther into X-ray beam.

nodules are the  $[0001]$  direction normal to the basal planes of graphite.

The picture of the structure that is formed is, therefore, one of aggregates of crystallites. Within each aggregate the  $c$  axes of the crystallites tend to align themselves in the radial direction of the nodule, although these axes deviate somewhat in direction by a continuous variation of angle. Correspondingly the basal planes of the graphite crystallites are generally normal to the radii.

It is a pleasure to acknowledge the assistance of M. C. Bloom and R. P. Dunphy of this laboratory.

# Deformation and Recrystallization Texture Of Cold-Drawn OFHC Copper Wire

by W. A. Backofen

THE texture of cold-drawn copper wire has been described most often as a composite of  $[111]$  and  $[100]$  directions aligned parallel to the wire axis.<sup>1</sup> Hibbard<sup>2</sup> suggested that sufficient reduction will result in a single  $[111]$  texture and reported that after a reduction in area of 96.4 pct, such a texture was nearly obtained. Other work<sup>3, 4</sup> has shown that recrystallization within the temperature range of 300° to 1000°C does not alter the texture established by cold-drawing. In general, however,

directions aligned parallel to the wire axis. Supplementary measurements with a Geiger-Mueller counter of the intensity of reflection from  $(111)$  planes showed that the  $[111]$  component was much more predominant than the  $[100]$ .

Additional specimens of the drawn and etched wire were annealed in a salt bath at temperatures from 300° to 450°C. The texture of the recrystallized wire was studied with the same technique applied to the cold-drawn wire. Fig. 1b is an X-ray

Fig. 1—X-ray photograph of OFHC copper wire.

a (left)—Cold-drawn 97.3 pct. b (right)—Cold-drawn 97.3 pct and annealed for 1½ hr at 300°C.

The wire axis is in the vertical position. The inner diffraction ring is from  $\{111\}$  planes. The outer diffraction ring is from  $\{200\}$  planes.

the texture of cold-drawn and annealed copper wire is not as well defined as the deformation texture. In the work reported here it was found that the double-fiber, deformation texture persists even after a reduction in area of 97.3 pct, and after recrystallization the texture is practically all  $[100]$ .

The wire used in this work was prepared in the following way. A ¾-in. diam length of annealed OFHC copper was cold-drawn to a diameter of ⅛ in., a reduction in area of 97.3 pct. Each step in the drawing operation brought about a reduction in area that varied from 6 to 10 pct. Short lengths of this wire were etched in a 50-pct solution of nitric acid to a diameter of approximately 0.01 in.

The texture of the cold-drawn specimens was determined with the conventional X-ray transmission diffraction technique using filtered copper radiation. The X-ray beam was directed perpendicularly to the wire axis and the diffraction rings were recorded on a flat film. Fig. 1a is typical of the photographs obtained and reveals that the cold-drawing schedule described above introduces a distinct, double-fiber texture with both  $[111]$  and  $[100]$

photogram of a specimen annealed for 1½ hr at 300°C and is typical of those obtained from recrystallized specimens. The photogram shows that recrystallization of this material is accompanied by the almost complete elimination of the  $[111]$  component of the deformation texture. A pronounced strengthening of the  $[100]$  component was evident from intensity measurements with a Geiger-Mueller counter.

In summary, the deformation texture of cold-drawn OFHC copper wire, after a reduction in area of 97.3 pct, may still be described as a composite of  $[111]$  and  $[100]$  directions aligned parallel to the wire axis. Recrystallization of such wire at temperatures from 300° to 450°C introduces a texture which consists almost entirely of a  $[100]$  alignment.

## Acknowledgment

Sidney Rolle of the Scomet Engineering Co. generously supplied the OFHC copper used in this work.

# Intergranular Energy of Iron and Some Iron Alloys

by Lawrence H. Van Vlack

The energy of the  $\gamma$ -iron grain boundary was determined to be 850 ergs per  $\text{cm}^2$  at  $1105^\circ\text{C}$ . The  $\alpha/\alpha$  and the  $\alpha/\gamma$  boundaries possess somewhat less energy. The microstructures of several iron alloys are discussed in terms of the interfacial energy relationships.

THE dependence of the shape of liquid interfaces upon their energies has been studied for some time.<sup>1-3</sup> Recently, Smith<sup>4</sup> concluded that many of the microstructures observed in metals may be attributed to the energies of the interfaces between the grains and phases.

While the energies of liquid surfaces have been measured by numerous different methods,<sup>5</sup> only two attempts have been made to determine experimentally the energy of surfaces involving crystalline solids. Udin, Shaler, and Wulff<sup>6</sup> used a procedure introduced by Berggren<sup>7</sup> to measure the surface tension of solid copper. It consisted of determining the load required on a thin copper wire so that the surface tension was counteracted, and no net strain resulted. Bailey and Watkins<sup>8</sup> used a different technique and were able to determine both the surface tension of copper and the tension of the copper grain boundary. They measured the contact angle which liquid lead makes against a copper surface. They then calculated the above energies from the surface energy of liquid lead by using the Pb vs. Cu/Cu\* dihedral angle and the surface groove angle formed during thermal etching. They obtained a value of 1800 dynes per cm for the surface tension of clean copper and approximately 640 dynes per cm for the tension of copper grain boundaries. The former value was somewhat higher than Udin's value of 1500 dynes per cm.

This paper includes a determination of the energy of the  $\gamma$ -iron grain boundary. In addition, the microstructural relationships of several other metallic and nonmetallic phases with iron were examined and an attempt was made to interpret the observed structures in terms of interfacial energy relationships.

## Theoretical Considerations

In a three-phase material containing a solid and two liquids, there may be two solid/liquid interfaces, one liquid/liquid interface and one inter-

granular interface. Liquid/liquid interfacial energies can be measured directly. Therefore, by determining the energy of such an interface and by measuring the required interfacial angles,<sup>9</sup> the energies of the interfaces involving solids may be obtained.<sup>10</sup> They may be shown schematically as in Fig. 1.

The above procedure requires the following assumptions: 1—The interfacial energies are, in general, unaffected by boundary orientation, and 2—the shapes of the interfaces are unaltered between annealing and sectioning for microscopic examination. The first assumption is good to a first approximation as shown by Dunn and Lionetti<sup>11</sup> except for a few critically orientated boundaries. Two conditions may alter the shape of a boundary upon cooling: 1—Precipitation of dissolved material upon one side of the interface, and 2—a change in volume during the transition from one phase modification to another. The former must be detected by microscopic observation. The latter may become appreciable in systems containing an interface between two liquids which solidify after annealing. However, possible movement of the two-liquid interface may be checked in the system diagrammed in Fig. 1 by measuring  $\theta$ , for example, and comparing it with its value as calculated from the other interfacial angles by:

$$\tan \theta_2 = \frac{-\sin \theta_3}{\cos \frac{\theta_5}{2}} + \cos \theta_2 \quad [1]$$
$$\cos \frac{\theta_4}{2}$$

The choice of a suitable pair of liquids is limited by several factors. The relative values of the several

LAWRENCE H. VAN VLACK is associated with the U. S. Steel Co., South Works, Chicago.

Discussion of this paper, TP 3029E, may be sent (2 copies) to AIME by May 1, 1951. Manuscript, Oct. 9, 1950; revision, Jan. 12, 1951. St. Louis Meeting, February 1951.

This paper represents part of a thesis by the author submitted in partial fulfillment of requirements of the degree of Doctor of Philosophy to the University of Chicago.

\* This notation, first employed by Smith<sup>4</sup> and followed by others, indicates the angle formed by one phase between the two adjacent grains (or phases).

interfacial energies should be such that the interfacial angles— $\theta_s$ ,  $\theta_1$ , and  $\theta_2$ —are as small as possible but still are greater than zero. The interface should be mobile enough so that it adjusts to the equilibrium shape in a reasonably short length of time. In addition, neither liquid should react with the solid to give a fourth phase.

Few liquid pairs contain all the above features. The two liquids, "copper" and "copper sulphide," most nearly met the requirements for use with iron. As such, they were not pure liquids, as shown in Fig. 2. Likewise, the iron surface became saturated with copper and sulphur.

The interfacial energy,  $\gamma$ , between liquid "copper" and liquid "copper sulphide" was measured by the differential capillary depression of their interface in two fused-silica tubes of unequal radii, as diagrammed in Fig. 3, in which:

$$\gamma = \frac{\Delta H g (D-d)}{2 \cos \phi} \frac{(b_1 b_2)}{b_2 - b_1} \tag{2}$$

The contact angle,  $\phi$ , with these phases was  $180^\circ$  (or  $0^\circ$  as the case may be). The difference in meniscus levels,  $\Delta H$ , was determined radiographically;  $D$  and  $d$  are the densities of the two liquids;  $g$  is  $980.6 \text{ cm per sec}^2$ ; and  $b_1$  and  $b_2$  were the radii of curvatures for the centers of the two menisci.

The radii of curvatures were not identical with the tube radii because the capillaries and the density differentials were too large for the menisci to approximate a hemisphere. However, the shape of a meniscus surface with a contact angle of  $180^\circ$  is the same as the surface of a drop with a contact angle of  $90^\circ$ , as shown in Fig. 4. Therefore, the radii of surface curvature may be calculated from the tube radii and the approximate capillary constant by following Sugden's<sup>13</sup> treatment of Bashforth and Adams' tables.

### Experimental Technique

The procedure chosen for the determination of the intergranular energy of iron required two separate experiments: 1—A determination of the relative energies of the several interfaces in an iron-copper-copper sulphide alloy, and 2—a determination of the energy of the liquid copper/liquid copper sulphide interface.

The former was obtained from the dihedral angles in a sample containing the three phases. The angles were measured with a protractor on a rotating micrometer ocular at a magnification of about X600. At least 100, and as many as 200, angles were measured between each of the required interfaces. Following Harker and Parker's work<sup>9</sup> the most

frequently observed angles were considered to be within  $\pm 5^\circ$  of the true interfacial angle.

The samples for microscopic examination were made by inserting iron and copper filings and sulphur powder into an iron crucible which was made by drilling a 3/32 in. hole into a 3/16 in. iron rod. These were compressed with a tapered iron plug. The latter also served to retain, first the sulphur, and then later the liquid in the compact during the annealing. The iron used was Puron which contained 0.17 pct O by vacuum fusion analysis and about 0.1 pct other elements. The copper contained 0.008 pct Fe and smaller traces of Ni, Si, and Ag. The copper sulphide was made both by subjecting the above copper to sulphur vapors in an evacuated sealed tube at  $500^\circ\text{C}$  and by mixing copper and sulphur in the compacts.

Fig. 5 gives the diagrammatic layout of the furnace equipment. The specimens were annealed under a hydrogen atmosphere and quenched into a water stream. Temperatures were measured with chromel-alumel thermocouples within the radiation muffles.

The capillary depression of the two-liquid interface was obtained under a nitrogen atmosphere after initial evacuation. After the copper and copper sulphide had melted, the two capillaries, 1 in. long, were pushed through the two-liquid interface by an iron weight. This iron weight and iron in the bottom of the crucible also served to saturate the liquids with iron. The crucible tube was placed in the furnace in a position so that a minimum amount of "copper" or "copper sulphide" masked the menisci. The liquids were allowed to stand at least 30 min before the X-ray exposure, during which time the crucible was vibrated at intervals so that better assurance of correct meniscus differentials was obtained.

The liquid densities were measured by determining the maximum pressures required to bubble nitrogen through different depths of the liquids, as shown in Fig. 6.

| 7—Trap and bubbler           |                            |

The radii of the capillaries were used to calculate the radii of curvature of the two-liquid interface at the crown of the menisci. The former were measured as two perpendicular diameters at each end of the 1-in. capillary tube.

### Energy of the Two-Liquid Interface

The density determinations required for the calculation of the interfacial energies are presented in Table I. The energies of the interface between liquid copper and liquid copper sulphide at several temperatures are given in Table II. The energies were determined for both iron-saturated and iron-free liquids.

The energy of the interface decreased with increasing temperature over the temperature range examined, as shown in Fig. 7. This decrease would continue to zero near the critical temperature where the two liquids become mutually miscible.<sup>5</sup> Reuleaux<sup>12</sup> showed that this critical temperature is slightly above 1400°C when the two liquids in the Cu-Fe-S system are saturated with iron, as indi-

cated in Fig. 2. An extrapolation of the interfacial energies between the iron-saturated liquids to zero at the critical temperatures is in accordance with the above expectations. The interfacial energy of the iron-free liquids decreased less with increased temperatures than did the energy between the iron-saturated liquids.

### Intergranular Energy of $\gamma$ Iron

The observed dihedral angles, from which the relative energies of the interfaces in the three-phase Fe-Cu-Cu<sub>2</sub>S alloy were determined, are shown in Fig. 8 as frequency distribution plots. In addition to the plots for the five angles to the nearest 10°, Fig. 8A to 8E, the dihedral angles observed for Fe vs. Cu/Cu<sub>2</sub>S were plotted to the nearest 2°. While the resulting accuracy was not increased propor-

| Cu <sub>2</sub> S vs. Fe/Fe | 25°      |                      |

Table IV. Interfacial Energies of the Fe-Cu-Cu<sub>2</sub>S Alloy at 1105°C

| Interface                             | Energy, Ergs per Cm <sup>2</sup> |
|---------------------------------------|----------------------------------|
| Liquid copper/liquid copper sulphide  | 100                              |
| Liquid copper/ $\gamma$ iron          | 430                              |
| Liquid copper sulphide/ $\gamma$ iron | 470                              |
| $\gamma$ iron/ $\gamma$ iron          | 850                              |

tionally in the latter case, the smaller overall variation in observed angles did permit a closer estimation of the true dihedral angle. This was desirable because it is a large angle and its sine function is used in the calculation of the relative interfacial energies.

There is evidence that the two-liquid interface moved on solidification. On the basis of the relative interfacial energies of the two iron-liquid interfaces as determined from the dihedral angles of the two liquids between iron grains, the Cu<sub>2</sub>S vs. Fe/Cu dihedral angle decreased about 15°, as given in Table III. The Cu vs. Fe/Cu<sub>2</sub>S angle increased by a similar amount. This movement may be associated with the lower specific volume of the solid, since the interface moved toward the copper sulphide which solidified first. It would not be expected that all of the two-liquid interfaces would be moved to give identical solid interfacial angles. The breadth of the frequency distribution curves, shown in Fig. 8C and 8D, supports this expectation.

Inasmuch as there was an apparent movement of the two-liquid interface during solidification, the relative and calculated dihedral energies were determined on the basis of the angles between interfaces involving a solid. These energies for the alloy of  $\gamma$  iron, liquid copper, and liquid copper sulphide at 1105°C are given in Table IV. It may be pointed

Table V. Dihedral Angles of Cu-Fe Alloys

| Test | Temperature, °C | Dihedral Angle             | Observed |

| 825             | $\alpha/\alpha$    | 0.85              |
| 1160            | Liquid/ $\gamma$   | 0.51 <sub>7</sub> |
| 1220            | Liquid/ $\gamma$   | 0.51 <sub>7</sub> |

\* Reference value.

out, however, that since the interfacial angles involving the two-liquid interface were near 90°, and their sine function was concerned, errors corrected by this precaution were relatively small. For example, the energy of the liquid copper/ $\gamma$ -iron interface would have been 470 ergs per cm<sup>2</sup> instead of 430 ergs per cm<sup>2</sup>.

An effort was made to determine the intergranular energy of iron at higher temperatures. However, at temperatures much above 1090°C, where the two liquids form, iron precipitated from the liquid copper sulphide onto the iron interface during quenching to obliterate partially the original iron/copper sulphide interface. This happened even with the most severe quench. Consequently, the relative interfacial energies were not estimated for the higher temperatures.

The accuracies of the calculated interfacial energies in Table IV are limited chiefly by the accuracy in the measurement of the Fe vs. Cu/Cu<sub>2</sub>S dihedral angle. A 15 pct possible error exists with a 2° error in that angle. An approximate check on the above value of 850 ergs per cm<sup>2</sup> for the intergranular energy of  $\gamma$  iron at 1105°C may be obtained from Bailey and Watkins<sup>8</sup> determination of the copper grain boundary energy. From the dihedral angle measurements, the relative energies of the iron and copper grain boundaries in iron-copper alloys at

Fig. 7—Energy of the liquid Cu/liquid  $\text{Cu}_2\text{S}$  interface.

1000°C are 1.0 and 0.7 respectively, Tables V and VI. Therefore, using their approximate value of 640 ergs per  $\text{cm}^2$  for the energy of the copper grain boundary, the intergranular energy of copper-saturated iron would be 915 ergs per  $\text{cm}^2$ .

### Relative Intergranular Energies of $\alpha$ and $\gamma$ Iron

The above measurements for the intergranular energy of iron were made on copper-saturated  $\gamma$  iron. Alpha iron cannot be in equilibrium with the

copper-saturated  $\gamma$  iron,<sup>14</sup> and a liquid pair was not found which was suitable for use in the temperature range of  $\alpha$  iron without the addition of ferrite-forming alloying elements. However, if it may be assumed that the energy of the copper grain boundary is somewhat constant with lowering temperatures, the relative intergranular energy of  $\alpha$  and  $\gamma$  iron may be determined by annealing copper-iron alloys below their eutectoid temperature. This gives a value for the  $\alpha$ -iron grain boundary as 0.85 that of the  $\gamma$ -iron boundary, as shown in Tables V and VI.

A more direct comparison of the energy of the  $\alpha$  and  $\gamma$ -iron grain boundaries may be made by measuring the dihedral angles in a duplex,  $\alpha$ - $\gamma$  alloy. This was done by adding 4 pct Si and 0.2 pct C to ingot iron. To give a third phase, 0.26 pct S was added and thus offered a means of checking the relative values.<sup>4</sup> See Fig. 10. Table VII shows these values for the recrystallized alloys at 1150°C. These are calculated from the interfacial angles shown in Fig. 9.

The energy of the  $\alpha/\alpha$  boundary is about 0.9 that of the  $\gamma/\gamma$  boundary. The  $\alpha/\gamma$  boundary energy was less than either the  $\alpha/\alpha$ , or the  $\gamma/\gamma$  boundary energy—about 0.7 of the latter.

The discrepancy appearing in the relative values of the energy of the  $\alpha/\alpha$  boundary as determined by the two methods must be attributed, at least in part,

Fig. 8—Test No. 252. Distribution of the observed dihedral angles in the Fe-Cu- $\text{Cu}_2\text{S}$  alloy. Annealed at 1105°C for 1 hr and quenched.

to the differences in compositions of the iron phase in the presence of silicon and copper.

The appearance of the duplex,  $\alpha$ - $\gamma$  alloy, given in Fig. 11, suggests that there is an orientation of the two-phase boundary with lower interfacial energy. On solidification, an alloy of this composition forms chiefly ferrite, but on cooling, austenite forms from part of the ferrite.<sup>15</sup> As indicated in Fig. 11, this proceeds along specific crystal directions. Annealing for extended periods of time does not reduce the interfacial area noticeably. Presumably an increase in energy would be required to move the interface even though a reduction of surface area would be obtained. If the alloy is recrystallized by hot working in the same temperature range, this preferred boundary orientation disappears and a normal two-phase structure is obtained, shown in Fig. 12.

### Relative Energies of Iron/Liquid Interfaces

**Sulphur-Containing Liquids:** The distribution of an iron-sulphur liquid in iron alloys has been of interest to metallurgists. In order to gain some information regarding the effect of interfacial energies upon this distribution, a series of samples, which were quenched from their annealing temperatures, were examined microscopically. The dihedral angles formed between iron grains by liquids containing iron sulphide at several temperatures above the eutectic are given in Table VIII.

The iron used in this case had been remelted under hydrogen to remove essentially all of the oxygen. At 1300°C, the liquid spread between most of the iron grains, as shown in Fig. 13, indicating that the energy of the liquid-iron interface had decreased to one half, or less, of the intergranular energy of iron. Some fewer obvious exceptions are

illustrated by Fig. 13 where the observed dihedral angles were still finite. Presumably a slight variation existed in the boundary energies with orientation, and as such, all of the dihedral angles did not become zero at once.

The decrease of the relative energy of the liquid-iron interface with increasing temperature cannot be assigned to the temperature rise alone.<sup>16</sup> The composition of the liquid changes to higher iron contents along the liquidus of the iron-iron sulphide system.<sup>17</sup> In that situation, there is greater similarity between the composition of the two phases so that atoms at the interface require less additional energy by virtue of their position.

The presence of oxygen in the sulphide-containing liquid showed comparatively little effect on the relative liquid/iron interfacial energy at temperatures below 1200°C, as given in Table IX. However, at 1300°C, the dihedral angle did not drop to zero as it did with the oxygen-free liquid, shown in Fig. 15. The explanation of this difference may lie with the liquidus relationships in the Fe-FeS-FeO system. On the basis of Vogel and Fulling's<sup>18</sup> and Gurry,

\* Fig. 14.

Darken and Anderson's<sup>19</sup> work, the liquidus isotherms for this system are shown in Fig. 14. The oxygen-free liquid is richer in iron than the oxygen-containing liquid at 1300°C. This difference is not so marked at 1200°C or lower.

A phase consisting of equimolecular amounts of FeS and FeTe may be liquid in the presence of  $\alpha$  iron. Thus, a general comparison of the relative interfacial energies, liquid/solid and solid/solid may be made when the solid is either  $\alpha$  or  $\gamma$  iron. In both

cases the liquid/iron interfacial energies are similar and slightly over one half of the iron/iron energy, see Table X. A direct comparison may not be made between the intergranular energy of the  $\alpha$  and  $\gamma$  iron from this data, however, because the liquid/solid interfaces are not identical in each case.

Some alloying elements appear to have an effect upon the shape of the sulphide liquids between the iron grains. The sulphide liquid in the high silicon  $\alpha$ - $\gamma$  alloy described previously, Fig. 10, showed relatively high interfacial energies with the two iron phases. The energies were approximately two thirds that of the  $\alpha/\alpha$  or  $\gamma/\gamma$  intergranular energy. Likewise, Sims<sup>30</sup> found microstructures which might be interpreted to result from higher liquid/iron interfacial energies in steels which were silicon-killed.

**Metal Liquids:** Liquid copper will infiltrate into iron compacts<sup>21</sup> and will form a relatively small dihedral angle between iron grains. These features have been assigned to the interfacial energy relationships. The solubility of iron in copper does not increase markedly under 1250°C.<sup>14</sup> Consequently, it may be anticipated that the energy of the liquid-copper/ $\gamma$ -iron interface is relatively constant be-

Table X. Relative Interfacial Energies of Liquid Sulphide-Telluride\*/Iron Interfaces

\*S = Te (atomic percent)

low that temperature. This was observed to be true on the basis of dihedral angles which were formed, Tables V and VI.

An addition of silver to liquid copper materially increases the liquid/iron interfacial energy until, in silver-rich liquids, the dihedral angle is near 180°. Likewise liquid lead, bismuth, and cadmium form dihedral angles between iron grains which are near 180°, indicating that the liquid/iron interfacial energy is relatively large. Iron is essentially insoluble in all of these liquids.

The difference in energies of the copper/iron and silver/iron interfaces cause the contact angles which these two liquids make with iron surfaces to differ. Molten copper has a 0° contact angle against iron in hydrogen. Molten silver has a contact angle of approximately 90°. From these relationships, it may be assumed that the surface energy of  $\gamma$  iron is approximately the same as the iron/silver interfacial energy and equal to, or greater than, the sum<sup>5</sup> of the iron/copper interfacial energy and the surface energy of liquid copper.†

#### Movement of Iron Interfaces

Smith<sup>4</sup> suggests three possible methods by which an interface between two phases may move to approach an equilibrium shape. 1—The atoms of one phase may diffuse through the other phase from positions of high surface energy to positions of lower

† By making the broad assumption that iron does not alter Sauerwalds<sup>22</sup> value of 1120 ergs per cm<sup>2</sup> for the surface energy of molten copper, a rough estimate for the minimum value for the surface energy of copper-saturated iron would be 1550 ergs per cm<sup>2</sup>.

Fig. 13—Test No. 277. Iron sulphide liquid in iron oxide-free iron.

Annealed at 1325°C for 30 min and quenched. X500. Area reduced approximately 33 pct for reproduction.

surface energy. 2—This diffusion may proceed along the interface rather than through an adjacent phase. 3—The interfacial energies are sufficient to deform plastically the materials into shapes of minimum surface energies.

The diffusion processes appear to be the more significant methods of interfacial movement in the liquid-iron systems studied. For example, the energies associated with the liquid-silver/iron or liquid-cadmium/iron interface are relatively high as shown by the large dihedral angles they form between iron grains. Yet with these higher energies, the silver/iron interfaces did not readily conform to equilibrium shapes, as shown in Fig. 16. Likewise, angular iron grains in liquid cadmium did not spheroidize by plastic deformation. At the same temperature, the interface between iron and an iron sulphide liquid conformed readily to the interfacial forces although the energy of the interface was relatively low, as shown in Fig. 17. The iron must be dissolved and reprecipitated through the liquid phase or along the liquid interface to move the interface.

The grain boundaries in iron appeared to be influenced by the presence of iron oxide inclusions, Fig. 18. Three times as many inclusions were observed on the convex side of the  $\alpha$ -iron boundaries as on the concave side, as given in Table XI. The convex side would be behind the grain boundary if the grain boundaries may be assumed to move toward their center of curvatures.<sup>9</sup> Presumably the grain boundary moved forward more rapidly when it first came in contact with the inclusion, because

the curvature of the surface became much sharper as the boundary assumed a position essentially normal to the inclusion surface. When the boundary, as a whole, moved beyond the inclusion, the curvature in the immediate vicinity of the inclusion was first decreased and then reversed. As such, the boundary was halted locally, leaving the majority of the grain boundary inclusions in the observed positions. The austenitic grain growth inhibition in steels, which is attributed to alumina inclusions,<sup>23</sup> quite possibly results from this type of boundary retention. There the inclusion size is markedly smaller. As a result the grain growth is controlled by a relatively small inclusion volume.<sup>24</sup>

### Summary

The energy of the  $\gamma$ -iron grain boundary was determined, and the microstructures of iron containing several metallic and nonmetallic phases were examined with an attempt to interpret some of the observed structures in terms of the interfacial energy relationships.

To determine the energy of the  $\gamma$ -iron grain boundary, the interfacial energy between liquid copper and liquid copper sulphide was measured from the differential depression of their interface in two capillary tubes of unequal radii. The liquid copper/ $\gamma$ -iron, liquid copper sulphide/ $\gamma$ -iron, and  $\gamma$ -iron/ $\gamma$ -iron interfacial boundaries were then calculated from the dihedral angles—Fe vs. Cu/Cu<sub>2</sub>S, Cu vs. Fe/Fe, and Cu<sub>2</sub>S vs. Fe/Fe.

In addition to the differential depression of the menisci, which was determined by radiography, the densities of the two liquids, and the radii of curvatures of the menisci were required for the calculation of the energy of the two-liquid interface. The densities were measured from the pressures required to bubble nitrogen through the liquids. The radii of interfacial curvatures were calculated from the capillary radii by using Sugden's treatment of

Bashforth and Adams' tables. The dihedral angles used were those most frequently observed in the microsection of a quenched sample.

The energy of the iron-saturated, two-liquid interface is 100 ergs per cm<sup>2</sup> at 1105°C, dropping to approximately 70 ergs per cm<sup>2</sup> at 1200°C. This decrease may be extrapolated to zero near the critical temperature slightly above 1400°C. At 1105°C, the following interfacial energies involving iron were established: Liquid copper/liquid copper sulphide, saturated with Fe, 100 ergs per cm<sup>2</sup>; liquid copper/ $\gamma$  iron, 430 ergs per cm<sup>2</sup>; liquid copper sulphide/ $\gamma$  iron, 470 ergs per cm<sup>2</sup>;  $\gamma$  iron/ $\gamma$  iron, saturated with Cu and S, 850 ergs per cm<sup>2</sup>.

In a duplex,  $\alpha$ - $\gamma$ , iron-silicon alloy the energy of the  $\alpha$ -iron grain boundary was observed to be 0.9 that of the  $\gamma$ -iron boundary. In an iron-copper alloy, the above value was 0.85. In the former alloy, the energy of the  $\alpha/\gamma$  boundary was 0.7 that of the  $\gamma$ -iron boundary.

The interfacial energy between  $\gamma$  iron and a sulphide liquid was a little greater than 0.5 that of the  $\gamma$ -iron/ $\gamma$ -iron energy at 1000° to 1200°C. Above 1200°C, the liquid-iron interfacial energy dropped to less than 0.5. When oxygen was present with sulphur in the liquid this relative energy did not drop to less than 0.5. Thus a noticeable difference in microstructure resulted because the liquid spread less extensively between the iron grains in the latter case.

Evidence is given showing that the movement of the solid/liquid interfaces in compliance with the interfacial energy results from diffusion, either through the liquid or along the phase boundary, and not from the plastic deformation of the solid.

Some evidence is given to show the manner by which inclusions in iron act as grain growth inhibitors.

### Acknowledgments

A large share of the work required for this study was done as an employee of Carnegie-Illinois Steel Corp. This was made possible through the efforts of E. W. Pierce and B. R. Queneau of South Works. All of this is gratefully appreciated. The generous guidance of C. S. Smith and the stimulating discussions with him and others of the Institute for the Study of Metals were indispensable. The facilities of both the Institute and South Works were made available.

## Technical Note

# Precipitation and Diffuse Scattering in an Fe-Mo-Co Alloy

by A. H. Geisler and F. E. Steigert

THE permanent magnet alloy comol, which contains 17 pct Mo, 12 pct Co, balance Fe, exhibits a precipitation reaction analogous to that at the iron end of the binary Fe-Mo system. The equilibrium precipitate, ( $P_s$ ), has a structure isomorphous with  $Fe_3Mo_8$  which is rhombohedral with parameters  $a = 8.97\text{\AA}$  and  $\alpha = 30^\circ 38.6'$  according to the work of Arnfelt and Westgren.<sup>1</sup> In the ternary alloy the parameters are  $a = 8.87\text{\AA}$  and  $\alpha = 31^\circ 0.5'$ . Oscillating crystal patterns of a single matrix crystal,  $M$ , in which  $P_s$  was precipitated by slow cooling from  $1300^\circ\text{C}$ , showed that the orientation relationship of the two lattices is as follows:

$$(\bar{1}\bar{1}0)_{P_s} // (110)_M$$

$$(11\bar{1})_{P_s} // (\bar{1}\bar{1}0)_M$$

There are crystallites of  $P_s$  in 12 different orientations in a single crystal of the parent solid solution. Microscopic examination shows that the crystallites are generally plate-like with their lateral dimensions parallel to  $\{110\}$  matrix planes.

When precipitation in a supersaturated alloy

quenched from  $1300^\circ\text{C}$  progressed isothermally at temperatures between  $600^\circ$  to  $800^\circ\text{C}$ , the evolution of the  $P_s$  structure could be traced. Diffuse diffraction effects in Laue patterns provided early evidence of the precipitation process. Analyses of these by a previously described technique<sup>2</sup> showed that they corresponded to rod-like elements parallel to  $\langle 110 \rangle$  matrix directions in reciprocal space. With further aging to promote growth of the precipitate, the rod-like elements contracted to points in reciprocal space for normal Bragg reflection from the precipitate as shown by the left diagram in Fig. 1. Thus the diffuse scattering was attributed to the small thickness of the plate-like particles which was inadequate for sharp diffraction. When the precipitate particles were first thick enough to give normal diffraction their structure was different from that of the equilibrium precipitate,  $P_s$ . The first structure,  $P_1$ , presumably is a coherent transition struc-

TN 69E. Manuscript, Nov. 1, 1950.

ture, for some of the rods pass through the (101) type points for the matrix showing that a precipitate reflection coincides with the (101) reflections and there are planes in  $P_1$  which have the same spacing as  $d_{101M}$ . Spacings of other planes in  $P_1$  are listed in Table I. Magnetic and mechanical hardening occur during the formation of  $P_1$ .

The coherent precipitate,  $P_1$ , subsequently transforms into a second structure,  $P_2$ , with interplanar spacings that resemble somewhat those of the  $\sigma$ -FeMo phase<sup>3</sup> as shown by the comparison of lines for  $\sigma$ -FeMo with those for specimens aged 18 hr at 700°C, or air cooled from 1300°C in Table I. There are certain similarities of the precipitates  $P_1$  and  $P_2$  which suggest that the second could form by simple readjustments of the first. Reflections Nos. 2 and 5 are common to the two. The structures are differentiated, however, by the slight splitting of the No. 5 reflection near  $(011)_M$  in the center diagram of Fig. 1 and by the absence of the two strong reflections

Nos. 1 and 6 near the  $(011)_M$  type reflections in Fig. 1. On the other hand, these two reflections for  $P_2$  agree with the  $(1\bar{1}0)$  and  $(11\bar{1})$  reflections for  $\text{Fe}_7\text{Mo}_6$ , the equilibrium precipitate,  $P_3$ , at the right in Fig. 1. The second precipitate, however, is differentiated from  $P_3$  by the presence for the former of the No. 5 reflection and the absence of the No. 3 reflections. The equilibrium precipitate,  $\text{Fe}_7\text{Mo}_6$ , forms during aging at the higher temperatures either isothermally or during slow cooling.

A proposed crystallographic mechanism of precipitation in this alloy awaits the solutions of the coherent structure and the sigma phase.

# Desulphurizing Molten Iron with Calcium Carbide

by S. D. Baumer and P. M. Hulme

IN the late thirties, the National Carbide Co. co-operated with C. E. Wood, of the U. S. Bureau of Mines, in his investigation of the relative merits of various desulphurizers, including soda ash, caustic soda, and calcium carbide. Laboratory tests showed that carbide, when it could be made to react, is an excellent desulphurizing agent for molten iron. Sulphur content can be driven to lower levels and higher extractions obtained with carbide than with any of the more common reagents. Wood's results<sup>1</sup> are shown in Table I.

Unfortunately, as the Handbook of Cupola Operation puts it, the chemical fact that carbide is a good desulphurizer was of only academic interest because it was found to be extremely difficult to devise a practical means to make it react with molten iron. Calcium carbide is formed in the electric furnace at 4000°F and above, and its softening point is probably at least 500°F above the usual working temperatures encountered in iron and steel practice. Consequently, carbide does not form a true slag but floats as a dry powder on top of the metal and only a very small portion of it ever comes in actual contact with the iron. Stirring with a rabble, or pouring the metal over the carbide, increases the efficiency only slightly. Extractions of 20 to 30 pct can be obtained in this manner, but conventional soda slag treatment can do better than this and do it more cheaply.

All attempts to lower the melting point of carbide in order to obtain a reactive, liquid slag have so far proved fruitless. Directly under the arc in a metallurgical electric furnace, carbide becomes highly reactive. Excellent sulphur removal can be obtained without any slag other than a thin layer of carbide.<sup>2</sup> Similarly, good results are obtained by adding small amounts of carbide to the finishing slag in double-slag arc furnace practice.

To react a liquid with a solid, it is axiomatic that the liquid has to wet the solid before anything can happen. If the solid is heavier than the liquid, the problem is easy, but it becomes more difficult when the solid is much lighter than the liquid, as in the case of carbide and liquid iron. Wood recognized this problem and solved it in a unique fashion. The results shown in Table I were obtained by spinning the carbide beneath the surface of the molten iron by means of a refractory centrifuge. This technique allowed each particle of the finely divided carbide to come into intimate contact with the metal and to be wetted thereby.

Wood's centrifuge technique was successful in the laboratory where it achieved excellent and consistent results. Some attempts were made to expand this method to commercial practice, but serious difficulty was encountered in obtaining a refractory centrifuge head that would be economically feasible.

Table I—Crucible Tests with the Mechanical Dispersing Unit

| Test No. | Sulphur in Metal, Pct |              |                  | Sulphur Removed, Pct | CaC <sub>2</sub> , Lb per Net Ton | Wt of Charge, G | Lb of CaC <sub>2</sub> per Lb of S Removed* |
|----------|-----------------------|--------------|------------------|----------------------|-----------------------------------|-----------------|---------------------------------------------|
|          | Initial               | 2-Min Sample | Final from Ingot |                      |                                   |                 |                                             |
| 126      | 0.097                 | 0.007        | 0.007            | 92.7                 | 10                                | 1600            | 5.56                                        |
| 127      | 0.083                 | 0.012        | 0.009            | 89.2                 | 10                                | 1600            | 6.75                                        |

\* This column calculated from Wood's figures<sup>1</sup> shown in rest of table.

About this time the war intervened and the project lay dormant for several years.

In 1944, it was revived. It was suggested that the carbide could be blown into the metal with a carrier gas in an attempt to eliminate the necessity for the expensive and brittle centrifuge. The idea was first tried out in a fairly large ladle of iron using natural gas as the carrier. Considerable sulphur was removed, but it was quite obvious that the use of natural gas was not practical.

Attempts then were made to blow carbide into molten iron using, in turn, nitrogen, argon, carbon dioxide, air, and oxygen. The latter two gases proved unsatisfactory. Calcium evidently prefers oxygen to sulphur because in the tests calcium oxide and carbon dioxide were produced, the sulphur still being untouched in the iron. Nitrogen, argon, and carbon dioxide gave much better results, although the efficiencies and extractions were erratic, and only a few isolated tests approached the results obtained by Wood. Table II shows typical results obtained with these gases. The sulphur removals were interesting, sometimes even encouraging, but it is evident that such erratic behavior could not be tolerated in commercial practice.

A number of different types of equipment, such as sand blasting machines, refractory guns, and the like were used to blow the solid into the metal. All types required relatively large quantities of gas in order to maintain the flow of solid carbide through the system and into the metal. It was observed that the bubbles of gas breaking through the surface of the metal contained quantities of unreacted carbide. The liquid metal never came in contact with these particles and if it cannot wet them it cannot react with them.

The initial work had shown that carbide had great possibilities as a desulphurizer. In practice

S. D. BAUMER is Manager and P. M. HULME, Member AIME, is Project Engineer, Technical Sales Dept., Air Reduction Sales Co., New York.

Discussion of this paper, TP 3034C, may be sent (2 copies) to AIME by June 1, 1951. Manuscript, Oct. 2, 1950. St. Louis Meeting, February 1951.

Fig. 1—Original screw feed carbide injection device.

the centrifuge method of injection could not be applied on an economical basis, but the blowing method showed definite possibilities, provided a method could be found to properly inject the carbide without the use of too much gas. With this consideration in mind, the real work of developing a process for using carbide as a desulphurizing agent in iron began.

### Apparatus Development

The first hand-operated apparatus, shown in Fig. 1, is merely a crude form of screw feed made from a carpenter's brace and bit and a few pieces of pipe. The apparatus was calibrated so that the weight of carbide delivered per revolution of the brace was known. Then, by counting the revolutions, it was possible to control the feed. Gas was introduced into the system at the end of the screw feeder and the flow controlled by a regulator and flowmeter. Carbon tubes of  $\frac{1}{2}$  in. ID were used for injection pipes.

Chateaugay pig, steel scrap, and iron sulphide were used to make up test heats which were melted in either a 100 or a 500-lb induction furnace. Analysis was adjusted to give an iron containing approximately 3.00 pct C, 0.150 S, 0.75 Mn, and 0.60 Si. When the metal was melted and the temperature reached 2650°F, any slag formed was skimmed off and the starting sample taken. The gas was started in the injection apparatus, the tube lowered into the metal and a predetermined amount of carbide injected into the melt.

The screw-feed method of introducing carbide enables the gas flow and the carbide flow to be independently controlled. It was found that particularly good results were obtained with only very light flows of gas. This is in marked contrast to the

blowing method which uses anywhere from 50 to 100 cu ft of gas per lb of carbide injected, as compared to as little as 0.25 cu ft per lb with the screw-feed method. With the screw-feed apparatus, crude as it was, results were obtained at once which compare in every way with those reported by Wood.

The next logical step was to put a small motor in place of the hand brace. After a few heats with this mechanized feeder, the present style feed mechanism was designed and built, as shown in Fig. 2. The principle is exactly the same as the hand-operated machine. The motor-operated screw is controlled by a Graham Variable Speed transmission capable of adjustment from 0 to 450 rpm. The whole mechanism can be raised or lowered by means of an air cylinder and can be rotated on a vertical axis through an arc of 150°. This was mounted between the 100 and 500-lb induction furnaces so that it could be used in either. The carbide hopper was placed directly on top of the feed mechanism above the sight-feed glass.

### Laboratory Results, 100 and 400-Lb Batches of Iron

Neither time nor resources were available to conduct a complete scientific research. The primary object of the laboratory work was to answer enough questions so that the pilot-plant stage could be started with some reasonable hope of success. The main question to be determined was: "Can 90 pct of the sulphur be removed from 3.00 pct carbon iron by means of calcium carbide on a basis which is economically competitive with other methods?" The results, Table III, indicate that it can be done.

Heat No. 96 was the first carbide heat using the hand feeder. At this stage it had not been learned how to salt the heat with sulphur to obtain high enough levels. However, it was quite encouraging to be able to take sulphur from 0.076 down to 0.005, a 93.5 pct extraction, in only 3 min. Three heats later, on heat No. 99, a phenomenal 98.7 pct extraction was obtained in 5 min with an expenditure of only 9.7 lb of carbide per lb of sulphur removed. During the course of this heat a most important point was observed. Injection time was 2.17 min and the sample taken directly after completion of injection analyzed 0.035 pct S. After waiting 5 min, the iron showed only 0.002 pct S.

Heat No. 100, not shown in the table, was run to test this. Carbide was injected at the rate of 1 lb per min for 1.5 min. A sample was then taken and the slag removed. This first sample showed a drop from the original 0.145 pct S to 0.045 pct S. After 2 min, a second sample analyzed 0.014 pct S and after 5 min, 0.008 pct S. At this time, there was some very light slag noticeable on the surface of the metal. This lead to the conclusion, which has subsequently been strengthened, that the calcium sulphide which is formed by dispersing carbide into the metal takes an appreciable time to float to the surface. Total sulphur is analyzed in the samples taken irrespective of whether it is in the form of iron or calcium sulphide. Therefore, although the reaction between the carbide and the sulphur is quite rapid, at least 8 to 10 min should be allowed after completion of injection in order to allow the metal to clear itself of the dispersed, finely divided calcium sulphide.

Heat No. 101 is interesting, not because the sulphur extraction is high, but because the starting sulphur is so high. Only 1 lb of carbide was injected and 130 points of sulphur removed at a ratio of 7.7 lb of carbide per lb of sulphur removed. On the next

Table II—Typical Results Using Carrier Gas Only  
Without Screw Feed

\* Sample taken from bottom of ladle.

heat, No. 102, 217 points were removed with a ratio of 6.0 lb carbide per lb of sulphur.

The question then arose: "Would soda ash, given the same opportunity to contact the iron, give comparable results?" Heat No. 116 answers that question. Lime, caustic soda, and mixtures of lime, soda ash, carbide, and spar were tried in turn, with equally unsatisfactory results.

Up to this point, 100 lb had constituted the standard heat. However, in order to test whether size had any effect on the results, a number of 400-lb heats were run in the 500-lb induction furnace with the results shown in heats No. 122 through No. 124. Rates of feed were increased from 0.6 to 0.8 lb per min up to as high as 6 lb per min. The extractions were all better than 90 pct and the ratios of pounds carbide per pound sulphur removed were good.

A series of tests then were run to determine whether or not dilution of the carbide with cheaper, finely divided lime would prove more economical than straight carbide. The best result obtained is shown in heat No. 135. In this heat a good extraction was obtained but far more carbide was used to obtain it than would be necessary if carbide alone had been used.

The effect of adding ferromanganese to the mixture is shown in heat No. 143.

The 2-in. OD, ½-in. ID carbon tubes being used were very satisfactory for this test work where they withstood several immersions of 2 to 3-min duration. Obviously, however, this material is unsuited to commercial operations where immersion times would be far longer and even continuous. A number of refractory coverings were tried and the best apparently was Korundal, a high-alumina product, put out by Harbison-Walker Co. Heats No. 150 through No. 169 were run using this type tube. Heats No. 150 through No. 156 show that tube material has little, if any, effect on the results either on 100 or 400-lb batches. On heat No. 161, a return to the idea of lime dilution was made with good extraction but poor carbide-sulphur ratio.

### Pilot-Plant Development

After observing the laboratory work and the results obtained, officials of the American Tube and Stamping Plant Div. of the Stanley Works, Bridgeport, Conn., made facilities available for testing the process on a pilot-plant scale.

Fig. 2—Carbide feed injection apparatus.

At Bridgeport, hot metal for the open hearths is produced in 54-in. cupolas. There are two cupolas which operate on a 72 to 96-hr cycle. While one is producing, the other is being relined. Metal flows at the rate of 12 tons per hr through a front-slugging trap into a holding ladle from which it is transferred, as needed, to the open hearths.

Some consideration was given to treating the hot metal in the transfer ladle. The average quantity transferred per ladle is 35,000 lb which, at 0.150 pct, gives a total content of 62.5 lb of sulphur. In order to extract 90 pct, or 56.25 lb, 562.5 lb of carbide would be necessary. The injection equipment, already developed, delivered carbide at a maximum rate of 20 lb per min, which meant that it would take more than 28 min to make the injection; this, plus a 10-min wait to clear the metal of calcium sulphide, would give a total of 38-min tie-up of the ladle. To design an injection machine for more rapid flows was not advisable at this stage. Because of its pos-

Fig. 3—Sketch of 1700-lb desulphurizing forehearth.

sible effect on needed production, all idea of carrying out test work in transfer ladle was abandoned.

It was decided to attempt to desulphurize the metal continuously as it left the cupola slag trap. A forehearth was installed parallel to the runner carrying the metal from the trap to the holding ladle; the stream of molten metal could be split to bypass a portion of the iron through this forehearth where it could be treated with carbide continuously by the same equipment used in the laboratory. The proportions of the forehearth were calculated to allow settling time for the calcium carbide to clear the metal. At the full rate of flow the capacity should be 4000 lb. This proved to be too large to fit into the available space. The largest forehearth which could be installed without interfering with production held 1700 lb. However, in order to get the information necessary, it was decided to build the 1700-lb forehearth although it was 15 pct too small to allow clearance of all the calcium sulphide formed in the reaction at metal flows of 6 tons per hr.

Fig. 3 shows a sketch of the forehearth, and Fig. 4 shows its position in relation to the cupola. It was a rectangular box made of  $\frac{1}{2}$ -in. welded steel plate, lined with  $2\frac{1}{2}$  in. of insulating brick next to the shell and faced with  $4\frac{1}{2}$  in. of chrome-magnesite brick in direct contact with the molten metal. The hearth area was 1 ft wide x 3 ft long, and the depth of metal was 15 in. at full 6 tons per hr flow. The hearth was divided by a submerged baffle into two

Fig. 4—Showing forehearth position with relation to cupola, slag trap, and runners.

sections. The untreated metal from the cupola runner flowed into the hearth on one side of this baffle where the injection of the fine carbide took place. The incoming metal and the churning action of the injected gas and carbide created considerable turbulence in this section, which gave the metal every opportunity to contact the solid carbide particles. The metal and the resulting slag rose and flowed over the dividing baffle to the outlet and skimming section of the hearth. Here the body of metal was relatively quiet and the solid particles of slag and calcium sulphide had an opportunity to float to the surface where they were skimmed off. The clean metal flowed out of the forehearth through a "teapot" spout which drew the metal from near the bottom of this section.

The whole forehearth was heated to working temperature before starting operations, but no firing was necessary after the full flow was attained.

A 1000-lb capacity carbide hopper, Fig. 5, was located between the cupolas on the charging floor level. Carbide flowed by gravity through a 2-in. gate

Fig. 5—A 1000-lb carbide hopper.

valve, and a 2-in. hose to the sight-feed glass above the screw-feed mechanism. A nitrogen atmosphere was maintained at about 8 psi maximum on the carbide hopper. This served both to keep the carbide dry and to balance the gas pressure in the entire system when the injection tube was immersed.

The injection tubes were made up as shown in Fig. 6. An extra-heavy-walled, welded 1-in. ID steel pipe served as the inner tube. To protect this working tube from metal and slag attack, it was fitted with refractory tubes similar to stopper rod sleeves. These were cemented in place by plastic chrome ore. The flared outlet nozzle was found essential to prevent bridging and plugging of the tube. The screw feeder was fitted with a revolution counter. The screw delivered a definite quantity per revolution, therefore the counter measured the pounds of carbide feed directly. The rate of feed was adjusted by means of the control wheel on the Graham Variable Speed Drive.

From the beginning of operations of the pilot plant, the chemistry compared favorably with the

batch operations on a laboratory scale. The basic figure of 10 lb of carbide per lb of sulphur removed was confirmed and while none of the continuous runs reached sulphur levels in the double "0" range, the 0.01 to 0.02 pct range was easily maintained. Because the forehearth was overloaded, it was felt that this caused some carry-over of calcium sulphide and that a larger hearth would produce lower sulphur levels and higher carbide efficiencies.

A typical run is shown in Fig. 7. At the start of the injection of carbide, there is 1700 lb of iron resident in the forehearth containing 0.176 pct S. The treatment begins to remove the sulphur from the metal and transfer it to the slag. At the same time, new metal containing 0.176 pct S is entering the system, and treated metal is leaving it at the same rate. As a result the sulphur comes down rapidly at first and gradually slows down, until a level of sulphur content is reached, where the rate of sulphur removal just balances the new sulphur coming in with the untreated metal. The rate at which this equilibrium can be reached is increased by increasing the carbide feed at the start of operations and then cutting back on the carbide feed until it is just sufficient to balance the incoming sulphur.

Fig. 8 shows how this is accomplished and also the effect of maintaining the balanced carbide feed

Fig. 6—Sketch of injection tube.

while increasing the rate of metal flow. As expected, the sulphur in the outgoing metal rises to a higher level. Naturally, therefore, when the metal flow is increased after balance is reached, the carbide feed rate must be increased in order to balance the sulphur at the desired low level.

The major difficulties were either mechanical or physical. It took considerable effort to evolve the relatively simple injection tube used. In the laboratory, carbon tubes of uniform bore had been used, but these would not stand more than 5 or 10 min of continuous immersion.

All refractory-covered tubes plugged after a few minutes immersion until the trick of flaring the exit end was discovered. Numerous types of refractory cover were tried, including graphite, clay-graphite, chrome, magnesite, mullite, zirconia, and clay. The best found was a fairly high silica clay, which is relatively cheap, stands the heat shock of immersion, and will last continuously in contact with the carbide slag from 4 to 5 hr. Changing a tube is a rapid and simple process so, while better tubes may be forthcoming at some future date, they will have to be really remarkable in their lasting powers to

Fig. 7—Typical pilot-plant run.

complete economically with the cheap clay tube. Fig. 9 shows a tube injecting carbide into the molten iron.

The slag formed was dry, crumbly, and quite voluminous. It did not run off even though its level was a number of inches above the skimming breast. It had to be dragged out mechanically. All attempts to add fluxing agents, such as spar, borax, etc., to the slag caused immediate and serious reversion of the sulphur to the metal. The slag, at first, was pulled off by hand rabbles into cast iron pots. Eventually, an air-operated rabble was built and the slag dragged off mechanically into a water trough which carried it to the slag dump-car. Fig. 10 shows the mechanical slagger in action, and Fig. 11 shows a general view of the entire pilot-plant assembly.

Trouble with the rabble heads was anticipated but it never materialized. When the slagging ma-

Fig. 8—Showing effect of increased feed rate at start and varying flow of iron.

Fig. 9—Tube working injecting carbide into molten iron.

chine was adjusted so that the bottom edge of the blade cleared the surface of the metal by about an inch, a head made of 1-in. steel plate lasted for hours. A light clay wash prevented serious sticking of slag on the head and, if some did accumulate, it was easily taken off with a sharp blow of a hammer.

Demand of the open hearths for metal, and other cupola operating circumstances apart from the pilot operation, made it impossible to get continuous runs of more than 5-hr duration. As stated above, space was strictly limited so that the wall thickness of the forehearth was relatively thin. The temperature loss by radiation in the system was quite large, amounting to about 100°F when the metal was run through the forehearth without carbide treatment. After starting carbide injection, the temperature loss rose to about 120°F at the start, and fell to about 100°F again when equilibrium was reached. This loss was of little importance to the pilot investigation as long as the flow of metal could be maintained. However, when the cupola had to be shut down for lack of immediate demand by the open hearths, the treatment forehearth had to be drained because of danger of serious skulling. For this rea-

Fig. 11—View of entire pilot-plant assembly.

son, the duration of the pilot-plant runs was limited. Nevertheless, there appears to be no reason to doubt that the process can be operated continuously for indefinite periods, if the forehearth is properly designed and the metal flow is reasonably consistent.

### Conclusions

1—Calcium carbide can be made to desulphurize molten iron either on a batch or a continuous flow operation.

2—When properly applied, it can consistently extract better than 90 pct of the sulphur content.

3—About 10 to 12 lb of carbide is required per pound of sulphur removed.

4—There was no reversion of sulphur to the metal from the carbide slag except when attempts were made to change the composition of the slag.

5—The efficiency appears to be independent of the sulphur level in the metal, and also independent of the temperature of the metal, at least in the range 2550° to 2850°F.

6—The process is more expensive than the conventional soda treatments. The cost will be from \$0.75 to \$2.00 per ton of metal treated, depending on the quantity of sulphur to be removed.

7—The process will drive sulphur content to lower levels more consistently than the conventional treatments. Sulphur levels in the 0.01 to 0.02 pct range and lower are easily attainable even when the starting sulphurs are as high as 0.200 pct.

8—When sulphur levels in the 0.06 to 0.08 pct range are satisfactory in the treated iron, the process is not competitive with the conventional treatments on a straight cost basis. Below this range, however, it appears to offer real possibilities.

### Acknowledgment

The authors wish to acknowledge the contributions made to the prosecution of this development by the following: J. F. Connors and his staff at the American Tube and Stamping Plant of the Stanley Works, Bridgeport, Conn.; H. R. Fisher and other members of the Air Reduction Research Laboratories, Murray Hill, N. J.; and J. M. Crockett and others of the General Technical Sales Department of the Air Reduction Sales Co., division of Air Reduction Co., Inc.

# Distribution of Sulphur Between Liquid Iron and Slags of Low Iron-Oxide Concentrations

by R. Rocca, N. J. Grant, and J. Chipman

**Desulphurization of liquid iron by reducing slags of the electric-furnace type was studied from 65 heats. Variations were made in basicity over a wide range and in FeO up to about 5 pct for their effects on desulphurization. The role of FeO in desulphurization from the blast furnace, to the electric furnace, to the oxidizing conditions of the open hearth is shown to fit a relatively simple pattern of behavior.**

THE mechanism which controls the desulphurization of molten iron by basic slags has been the object of several investigations. In particular, equilibrium determinations have been made both in the field of basic open-hearth slags, which have a high iron-oxide concentration, and in the field of blast-furnace slags which have a very low iron-oxide concentration. In both cases the desulphurization ratio has been found to increase with increasing basicity of the slags; however, the mechanism of desulphurization differs in the two cases.

In basic open-hearth slags desulphurization occurs mainly as a partition of iron sulphide:<sup>1</sup>

and the desulphurization ratio is approximately independent of iron-oxide concentration in the slag.

In blast-furnace slags the concentration of iron oxide is very low as a result of the highly reducing conditions in which they are formed. The controlling reaction for desulphurization is then:<sup>2, 3</sup>

The slags of the reducing stage in the electric furnace have an iron-oxide concentration which is intermediate between blast-furnace and open-hearth slags. The study of the mechanism of desulphurization for these slags has been the object of this investigation.

The importance of low (FeO) in the slag for desulphurization was first verified by Bardenheuer and Geller,<sup>4</sup> who found that high desulphurization ratios were obtained in highly reduced slags. It was recognized<sup>5, 6</sup> that iron oxide in the slag becomes a controlling factor in desulphurization only at FeO concentrations approximately under 5 pct. A recent

investigation conducted by Buehl,<sup>7</sup> upon the suggestion of one of the authors, confirmed this opinion from the results obtained from a heat conducted in a small arc furnace.

In the present investigation, slags of very high basicity, such as often are encountered in the basic electric furnace, could not be studied, but equilibrium data have been obtained for slags in a wide basicity range. The iron-oxide concentration in these slags ranged from 0.08 to 15 pct and was controlled by the addition of silicon to the metal. Other constituents of the slags were mainly CaO, MgO, SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>, and CaF<sub>2</sub>.

The experimental technique was essentially the same as that of previous investigations.<sup>1, 8-10</sup> In an open magnesia-lined induction furnace, 65 lb of Armco ingot iron was melted. An atmosphere of hydrogen was maintained over the melt for 1 hr to bring the carbon content down to approximately 0.010 pct maximum. The bath then was exposed to air for 25 min to remove hydrogen. The electrodes were put in place, and the furnace was operated from this point on in an atmosphere of nitrogen. A synthetic slag was added to which additions of silicon and iron sulphide were made. A rate study conducted at the beginning of this investigation had

R. ROCCA, Junior Member AIME, formerly Research Assistant in Metallurgy, Massachusetts Institute of Technology, is now in Milano, Italy. N. J. GRANT and J. CHIPMAN, Members AIME, are Associate Professor and Professor, respectively, Department of Metallurgy, Massachusetts Institute of Technology, Cambridge.

Discussion on this paper, TP 3035C, may be sent (2 copies) to AIME by June 1, 1951. Manuscript, Nov. 22, 1950. St. Louis Meeting, February 1951.

This paper represents part of a thesis by R. Rocca submitted in partial fulfillment of requirements for the degree of Doctor of Science to Massachusetts Institute of Technology.

Dash means not run.

shown that sulphur equilibrium was essentially approached within 30 min after the addition of iron sulphide, or after a change in the composition of the slag. Accordingly, samples were taken at 45 to 60 min intervals depending upon the apparent fluidity of the slag. Temperatures were measured just before sampling by means of tungsten-molybdenum thermocouples and are considered to be correct within 10°C. New additions to the slag or metal were made immediately after sampling, including silicon metal additions to maintain low oxidation values. All sampling was accomplished by the use of long-handled split steel molds of the type used in previous investigations.<sup>1, 8-10</sup>

The results of chemical analysis of the slag and metal samples are shown in Table I. All calcium present was calculated to CaO and CaF<sub>2</sub>.

Some metallic iron was present in the slags and was separated by passing the slag sample over a Frantz iso-dynamic separator four or five times. The magnetic separator yielded better results than the determination of metallic iron by the copper sulphate method, the latter method accounting apparently for only a fraction of the metallic iron present. The analyses of chemically combined iron are reported in Table I as iron oxide, although they include any iron sulphide present in the slag. The analytical uncertainty is believed to be  $\pm 0.02$  pct FeO. Other analyses were by conventional methods.

Although the data obtained, reported in Table I, are of the same order of accuracy of previous investigations,<sup>1, 8-10</sup> it is felt that the errors involved are somewhat higher. One of the main controlling factors was iron-oxide activity of the slag. Such activity could not be measured from the oxygen concentration in the metal, since the oxygen values were very low, and of the same order of magnitude as the accuracy of the vacuum-fusion analyses ( $\pm 0.002$  pct). Hence a measure of the oxygen activity would come only from the evaluation of the iron-oxide concentration in the slag. Moreover, although the furnace atmosphere was controlled closely, small amounts of oxidation were unavoidable. The iron-oxide concentration in the slag was probably shifting slowly and might not have been in complete equilibrium with the metal, especially with the most basic, and less fluid slags. The constancy of the sulphur ratio, after the first 30 min following an addition, was evidence that the desulphurization reaction reasonably approached equilibrium, even if others, such as the slow silicon reaction, were often far from equilibrium.

### Analysis of Experimental Data

In the chemical analysis of the slags, Table I, calcium present in the form of calcium sulphide was included in the total concentration of lime and was, therefore, considered to act as a base.<sup>2, 3</sup>

The most widely accepted mechanism of desulphurization, under reducing conditions, is expressed by the following reactions:

resulting in the overall reaction:

$$K = \frac{(a_s) \cdot (a_{\text{FeO}})}{a_s \cdot (a_{\text{CaO}})} \quad [4]$$

The activity of sulphur in the slag can be assumed to be approximately proportional to its weight percent, for low concentrations. The activity coefficient of sulphur in iron, in the presence of silicon, has been determined by Morris and Williams<sup>11</sup> and their values have been employed here for the computation of  $a_s$ . A more difficult task is involved in the calculation of the activity of iron oxide and lime in the slag, since our present knowledge of the structure of molten slags is more of a qualitative than of a quantitative nature.

On the basis of a molecular approach, FeO and CaF<sub>2</sub> were assumed to be neutral species. The basicity of the slags was expressed by a molar ratio for rough grading of the slags, defined as:

$$b = \frac{(\text{CaO}) + (\text{MgO})}{(\text{SiO}_2) + (\text{Al}_2\text{O}_3)}$$

The slags reported in Table I were divided on the basis of the value of this ratio into acid slags ( $b < 1$ ) and basic slags ( $b > 1$ ). Since the basic slags ranged in basicity from  $b = 1$  to  $b = 4$ , it was felt that two different calculation bases must be employed for the more basic and less basic slags. It was believed that a boundary line between the two could be drawn at a value of the basicity ratio somewhere near  $b = 2$ .

**Slags of High Basicity:** The molar composition of slags of higher basicity was calculated by neutralizing 1 mol of acids ( $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ ) with 2 mols of bases (CaO, MgO). It was assumed, therefore, that these slags contained the following undissociated compounds:  $2(\text{CaO}, \text{MgO}) \cdot \text{SiO}_2$ ;  $2(\text{CaO}, \text{MgO}) \cdot \text{Al}_2\text{O}_3$ ; CaO; MgO; FeO; CaF<sub>2</sub>. It was further assumed that the mol fractions of free CaO and MgO were in the same ratio as the ratio of their total amounts. The expression *excess* CaO is used to denote the mol fraction of free lime arbitrarily defined by this method of computation in accordance with a concept first introduced by Sherman and Grant.<sup>3</sup>

The sulphur ratio  $\frac{(\%S)}{a_s}$  is plotted in Fig. 1 vs.

mol pct FeO. The points corresponding to a basicity ratio  $b < 2.3$  could not be correlated in this manner; hence Fig. 1 represents only points characterized by a basicity ratio larger than 2.3. It is felt that the spread of the points is mostly imputable to inhomogeneities of these slags, which were the most basic and had a limited fluidity. The spread could not be reduced by a correlation with basicity ratio, excess base, temperature, or other variables. In particular, the (FeO) analysis for the point at  $(\%S)/a_s = 19.3$  is believed to be in excess of the true value. On the same figure the points represented by squares are average values obtained from the data of Grant and Chipman<sup>1</sup> for slags of equal value of "excess CaO" but higher (FeO) content; they fit the selected curves very well.

**Slags of Intermediate Basicity:** Slags included in this group range from 1 to 2.3 basicity ratio (all the leaner basic slags which were not plotted in Fig. 1). Their molar composition was calculated by neutralizing 1 mol of acids ( $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ ) with 1 mol of bases (CaO, MgO). It was assumed therefore that these slags contained the following undissociated compounds:  $(\text{CaO}, \text{MgO}) \cdot \text{SiO}_2$ ;  $(\text{CaO}, \text{MgO})$

Fig. 1—Effect of iron oxide in the slag upon desulphurization ratio for slags of higher basicity at  $T = 1600^\circ$  to  $1700^\circ\text{C}$ . Neutralization of the acids on 2:1 basis.

$\cdot\text{Al}_2\text{O}_3$ ;  $\text{CaO}$ ;  $\text{MgO}$ ;  $\text{FeO}$ ;  $\text{CaF}_2$ . Again, as for the slags of the preceding group, it was assumed that the mol fractions of free  $\text{CaO}$  and  $\text{MgO}$  were in the same ratio as the ratio of their total amounts. The expression *excess CaO* is used to denote the mol fraction of free lime arbitrarily defined by this method of computation.<sup>8</sup>

The sulphur ratio  $\frac{(\%S)}{a_S}$  is plotted in Fig. 2 vs.

mol pct (FeO). It can be seen that a good correlation is found between sulphur ratio, mol pct (FeO) and *excess CaO*. The point represented by a square and plotted on the same figure is the average value of the sulphur ratio obtained from the data of Grant and Chipman<sup>1</sup> for slags of corresponding basicity but higher (FeO) content.

### Discussion of Results

The data plotted in Figs. 1 and 2 cover all the experimental slags available from this investigation, for temperatures ranging from  $1550^\circ$  to  $1700^\circ\text{C}$ . They show that desulphurization is mainly controlled by two factors: Concentration of free lime, and concentration of iron oxide in the slag. The desulphurization ratio is increased by increasing amounts of free lime and by increasing reduction of the slag. The latter factor becomes controlling only at the low (FeO) concentrations, presumably when (FeO) is lower than 2 mol pct.

A more complete interpretation of these results will be obtained by considering the slags of intermediate basicity, which are plotted in Fig. 2. They represent the largest group of slags and therefore appear to be the best testing ground for the assumptions involved.

Magnesia has not been considered as an effective desulphurizer, but as a basic oxide, the effect of which is only to increase the basicity of the slag. A thermodynamic justification can be reached by

comparing the desulphurizing power of basic oxides, according to the reactions:

The equilibrium constants for these reactions have been calculated by Chipman.<sup>18</sup> At  $1600^\circ\text{C}$  they have the following values:

$$K_{\text{CaO}} = \frac{a_{\text{CaS}\cdot\text{O}}}{a_{\text{CaO}\cdot\text{S}}} = 0.04 \quad [7]$$

$$K_{\text{MgO}} = \frac{a_{\text{MgS}\cdot\text{O}}}{a_{\text{MgO}\cdot\text{S}}} = 1 \times 10^{-4} \quad [8]$$

Although exact data on the activities of oxides and sulphides in liquid slags are lacking, it is apparent that lime is about 1000 times a better desulphurizer than magnesia, when the desulphurization is controlled by the above reactions. This conclusion was confirmed by Sherman and Grant,<sup>3</sup> who found no effect of magnesia upon desulphurization in equilibrium blast-furnace slags. In basic open-hearth slags, the sulphur removal is mainly produced by the distribution of iron sulphide between slag and metal.<sup>1</sup> In this latter case the distribution ratio appears to be controlled by the *excess base*, as expressed by Grant and Chipman,<sup>1</sup> and magnesia may play an equal role with lime in increasing the basicity of the slag.

The shape of the curves plotted in Figs. 1 and 2 suggests that in the low (FeO) range desulphurization is controlled predominantly by reaction 3. This would imply the validity of the equilibrium constant  $K$  as expressed by eq 4. Under the simplifying assumptions employed, it is possible to define for each slag-metal couple an equilibrium product:

$$K' = \frac{(\%S) \cdot (\text{mol \% FeO})}{a_S \cdot (\text{excess CaO})} \quad [9]$$

Fig. 2—Effect of iron oxide in the slag upon desulphurization ratio for slags of intermediate basicity at  $T = 1550^\circ$  to  $1700^\circ\text{C}$ . Neutralization of acids on 1:1 basis.

Taking into account the prevailing sources of errors in the present investigation, the average value of  $K'$

can be best obtained from a plot of  $\frac{(\%S)}{a_s} \cdot (\text{mol } \%$

FeO) vs. (excess CaO). This plot is shown in Fig. 3. The points plotted represent all the slags of intermediate basicity ( $1 < b < 2.3$ ) which are also plotted in Fig. 2, with the exclusion of slags analyzing more than 2.3 mol pct FeO. The temperature range is 1550° to 1700°C. A differentiation of the points on the basis of temperature had shown, however, no significant trend; hence the effect of temperature is assumed to be small.

If  $K'$  were constant, the points would define a straight line, passing through the origin of the coordinates and with a slope equal to  $K'$ . It is clear, however, that the points plotted define a curve and a variable value of  $K'$ . This can be expected since the range of basicity covered is very large and varies from  $b = 1$  to  $b = 2.3$ . The plot of Fig. 3 shows that the points characterized by a basicity value ( $b$ ) above 1.9 diverged most from the ideal straight line, especially at the higher values of excess CaO. Such behavior can be accepted as evidence that the actual constitution of the liquid slag is not that indicated by the arbitrary formulas assumed in the present method of calculation.

A computation of the activities of slag constituents in a pure binary CaO-SiO<sub>2</sub> slag was carried out by Murray and White<sup>14</sup> on the basis of assumptions probably more accurate than those employed in the present calculations. Their values would show that near the orthosilicate composition the activity of "free CaO" increases more rapidly than the "excess CaO." This would justify, at least qualitatively, a deviation similar to that verified in Fig. 3.

The equilibrium blast-furnace slags studied by Hatch and Chipman<sup>2</sup> fall into the basicity range  $1 < b < 1.9$ , and they can be plotted in Fig. 3. For this plot, the value of excess CaO has been calculated in the same manner as for all other slags plotted in Fig. 3, namely on the basis of a 1:1 saturation of the bases. The points chosen are those taken at 1500°C and averaging 1.55 pct S in the slag. Sherman and Grant<sup>8</sup> have shown already that the ratio  $(\%S)/S$  was, for these slags, directly proportional to the (excess CaO). The value of the activity of sulphur in pig iron,  $a_{S_i}$ , is calculated by the use of the activity coefficient in the presence of carbon<sup>15</sup>  $f_{S_c}^S$  and in the presence of silicon<sup>11</sup>  $f_{S_{Si}}^S$ . It is assumed that, in the presence of both carbon and silicon, the resulting activity coefficient is the product of the two separate values:<sup>14</sup>

$$f_{C, Si}^S = f_{C_c}^S \cdot f_{S_{Si}}^S$$

An average activity coefficient of 5.7 is obtained, and the resulting ratio  $(\%S)/a_s$  yields values from 20 to 60 as compared with  $(\%S)/S = 100$  to 400. The blast-furnace slags<sup>2</sup> were analyzed again for FeO and averaged 0.027 to 0.030 wt pct (FeO); this corresponds to an average value of 0.040 for

the mol pct (FeO). The plot of  $\frac{(\%S)}{a_s} \cdot (\text{mol } \%$

FeO) vs. excess CaO for these slags is shown in Fig. 3 by the use of black squares. The points fit a

straight line, which can be extrapolated to the origin, and which also fits the points obtained in this investigation for  $1 < b < 1.9$ .

The agreement between blast-furnace slags and highly reducing slags of the electric-furnace range shows that in both cases desulphurization is controlled by eq 3. The value of the equilibrium product  $K'$  is obtained directly from the slope of the straight line in Fig. 3:

$$K' = 6.5 \quad \text{for } 1 < b < 1.9$$

$$\text{and } 0.040 < (\text{mol } \% \text{ FeO}) < 2.0 \quad [9a]$$

It also follows that the data obtained in the present investigation can be extrapolated to the blast-furnace range. This is shown by Fig. 4 in which the squares represent average values for blast-furnace slags at several excess CaO levels. The remaining points are plotted from Fig. 2. The plot is on a log-log basis, and the straight portion of the lines has an inclination of 45° in agreement with the approximate constancy of  $K'$ . The dashed line in Fig. 4 does not fit the blast-furnace data, although the value of excess CaO is the same for both. This is to be expected, since the blast-furnace slags under consideration all have  $b < 1.9$  and thus show a constant value of  $K'$ , while the points represented by the dashed line all have higher basicity and are those which deviate from the straight line in Fig. 3.

It is now possible to draw a comprehensive picture of desulphurization in all ranges of (FeO) concentration. Based on the molecular theory, desulphurization is controlled by the following reactions:

Under highly reducing conditions, as in the blast furnace, reaction 2 is pushed far to the right, and all or most of the sulphur in the slag is in the form of CaS. Pure partition of FeS plays a minor role, and, for all purposes of calculation, the sulphur in the slag in the form of (FeS) can be neglected.

In open-hearth and electric-furnace slags sulphur may be present both in the form of (FeS) and

Fig. 3—Influence of basicity on the equilibrium product  $K'$ . Neutralization of the acids on 1:1 basis.

Fig. 4—Extrapolation of the data for slags of intermediate basicity to the range of blast-furnace slags. Neutralization of the acids on 1:1 basis.

(CaS). The total desulphurization ratio then is given by the equation:

$$\frac{(\%S)}{a_s} = \frac{(\%S_{Fe}) + (\%S_{Ca})}{a_s} \quad [10]$$

and one may write, similarly to Bardenheuer and Geller<sup>4</sup> and Wentrup:<sup>16</sup>

$$\frac{(\%S)}{a_s} = L_{FeS} + K'' \cdot \frac{a_{CaO}}{a_{FeO}} \quad [11]$$

where:

$$L_{FeS} = \frac{(\%S_{Fe})}{a_s} \quad [12]$$

and:

$$K'' = \frac{(\%S_{Ca})}{a_s} \cdot \frac{a_{FeO}}{a_{CaO}} \quad [13]$$

The value of  $L_{FeS}$  depends on the composition of the slag, and it is difficult to evaluate it when part of the sulphur in the slag is in the form of  $(S_{Ca})$ . The only value known for  $L_{FeS}$  is that in pure iron oxide slag ( $L_{FeS} = 3.6$  at  $1600^\circ\text{C}$ ). For slags more basic than the orthosilicate composition, in the approximate range from 10 to 30 pct (FeO) the total desulphurization ratio appears to be independent of (FeO) concentration and excess base is the main

controlling factor.<sup>1</sup> A probable explanation of this result may be found in the high value of  $L_{FeS}$  for these slags: In particular, at high (FeO) concentrations,  $(S_{Ca})$  is only a fraction of the total sulphur in the slag, and  $(\%S)/a_s$  practically coincides with  $L_{FeS}$ . Furthermore,  $L_{FeS}$  is of the same order of magnitude as the partition coefficient for pure iron-oxide slag, so that additions of (FeO) do not affect it too significantly.

This is not the case for less basic slags like the slags of intermediate basicity which form the bulk of this investigation. The partition coefficient  $L_{FeS}$  is lowered with decreasing basicity of the slag, and the values of  $(S_{Ca})$  cannot be neglected as soon as they become of the same order of magnitude as  $(S_{Fe})$ . The influence of (FeO) on these slags cannot be merely that of a diluent, for high (FeO) concentrations, since the partition coefficient for pure iron-oxide slag may be many times higher than that of the original slag. Hence, addition of FeO to slags of intermediate basicity must increase their partition coefficient. The plot of desulphurization ratio in the ternary diagram FeO — (CaO + MgO) —  $\text{SiO}_2$ , as given by Fetter and Chipman,<sup>8</sup> also shows a similar trend. Experimental data on the variation of  $L_{FeS}$  with (FeO) concentration, for a slag of given basicity, are lacking however, and some simplifying assumptions are necessary. On the basis of the work of Bardenheuer and Geller,<sup>4</sup> one may consider  $L_{FeS}$  to vary linearly in the whole (FeO) range. It is then necessary only to estimate the value  $L_{FeS}^\circ$  that  $L_{FeS}$  will assume for (FeO) = 0, since it is known that  $L_{FeS} = 3.6$  when (FeO) = 100 pct (at  $1600^\circ\text{C}$ ). In the present case, values of  $L_{FeS}^\circ$  were assumed which would fit the points for the two lower lines in Fig. 4. Accordingly, it was determined at (FeO) = 0:

$$\begin{aligned} b = 1.7 & \quad L_{FeS}^\circ = 0.3 \\ b = 1.5 & \quad L_{FeS}^\circ = 0.1 \end{aligned}$$

The values reported for the basicity  $b$  correspond to an excess CaO (on 1:1 basis) = 0.15 and 0.10, respectively, for the high magnesia slags under consideration.

On the basis of the chosen values of  $L_{FeS}^\circ$  and of the linearity assumed for  $L_{FeS}$  in the range 0 to 100

pct (FeO), the values of  $\frac{(\%S_{Fe})}{a_s}$  are given directly in Fig. 5 as a function of mol pct (FeO).

It is now possible to solve eq 11 which, on the basis of the molecular assumptions employed, can be written as follows:

$$\frac{(\%S)}{a_s} = L_{FeS} + K' \frac{(\text{excess CaO})}{(\text{mol \% FeO})} \quad [11a]$$

The solution of this equation is shown in Fig. 6.

The values of  $L_{FeS} = \frac{(\%S_{Fe})}{a_s}$  are obtained from

Fig. 5 and are represented by the dashed lines which end at the point at  $\frac{(\%S)}{a_s} = 3.6$ , and (FeO) = 100

pct. The values of  $\frac{(\%S_{Ca})}{a_s} = K' \frac{(\text{excess CaO})}{(\text{mol \% FeO})}$

are expressed by the straight lines inclined at  $45^\circ$

Fig. 5—Assumed influence of (FeO) on the distribution coefficient of iron sulphide.

Fig. 6—Distribution of total sulphur as a function of iron oxide in the slag. Neutralization of the acids on 1:1 basis.

and represent an extrapolation from Fig. 4. The full lines in this diagram give the solution of eq 11a and have been obtained by addition of the corre-

sponding values of  $\frac{(\%S_{Fe})}{a_s}$  and  $\frac{(\%S_{Ca})}{a_s}$ . While

the lines traced for excess CaO = 0.10 and 0.15 stem from the application of definite assumptions, the line for excess CaO = 0.22 is purely hypothetical. All lines have been carried through to (FeO)

= 100 pct to show their common point at  $\frac{(\%S)}{a_s} =$

3.6; although the value of excess CaO vanishes as (% FeO) approaches 100 pct. The experimental points from the pertinent ranges of (excess CaO) are also plotted in Fig. 6. The fact that these points seem to substantiate the theoretical curves should not be taken as a proof of the correctness of the assumptions employed. The diagram is traced on a log-log basis and is greatly expanded in the range of the lower desulphurization ratios. In this range, other curves, which apparently would not be fitted by the points, might still be in good agreement with them, if plotted on a conventional scale. Thus values double those assumed for  $L_{FeS}^\circ$  could still be considered to fit the experimental data, although they would appear to disagree with them, on the basis of the plot of Fig. 6. The full lines in Fig. 6 show that the mechanism of desulphurization, in the full range of (FeO) concentrations, can be explained by the reaction 3.

It is further shown that the constancy of the desulphurizing ratio in a large range of (FeO) concentration does not imply a mere partition of FeS between slag and metal but is also verified on the hypothesis of the overall reaction 3. When the basicity is sufficiently high, the constancy of the desulphurization ratio is extended to a large range of (FeO) concentration. In this range, from the standpoint of calculations, it is indifferent whether desulphurization is carried out by a mechanism of pure partition, as expressed in eq 1, or by a reaction, as expressed in eq 3. This is shown in Fig. 7, in which the range of slags of basicity higher than 2 has been sketched in its estimated position. The slags investigated by Grant and Chipman<sup>1</sup> are outlined by the heavy lines, and it appears clearly that, for these slags, (FeO) has little effect on their desulphurizing power over a large range of iron oxide

concentration in the slag. Fig. 7 also illustrates how the different fields of steelmaking are connected by the desulphurization reaction. In the blast furnace, partition of FeS plays a minor role: In the open hearth it plays the main role. Finally, the reducing slags of the electric furnace represent the transition between the two prevailing mechanisms.

The previous discussion has been based on the assumption that molten slags are composed of molecular compounds and their constituent oxides. However, as already pointed out by Hatch and Chipman for blast-furnace slags,<sup>2</sup> this does not imply that the actual structure of molten slags is similar to that assumed in this discussion. On the contrary, it is more probable that the real structure of a slag is intermediate between an ideal ionic solution and a mixture of partially dissociated compounds. From the standpoint of calculations this would be equivalent to assuming a more complete dissociation of the compounds in the slag. The expression of equilibrium in terms of atoms or groups of atoms, instead of definite compounds, might lead to a more accurate evaluation of the experimental results, but in the actual state of investigations the pertinent data lack the necessary accuracy and still would need some more or less arbitrary assumptions. This is particularly true for the slag systems studied in the present investigations, which are high in silica and magnesia concentrations, and thus require the assumption of the formation of

Fig. 7—Desulphurizing power of basic steelmaking slags. Neutralization of the acids on 1:1 basis.

complex ions. For such a case simpler assumptions, similar to those employed in this investigation, seem to yield values of the activities of the different components which are probably proportional to the true values, in definite ranges of composition. It is clear however that their absolute values may not be comparable with the true values, outside of the criterion of limited proportionality outlined above.

Even if quantitative calculations appear problematical, the concept of ionization is useful for a qualitative analysis of the results. In the transition from acidic to basic solutions the silicate ions probably follow a series of steps:

and each step requires the addition of oxygen ions. Thus the number of relatively free oxygen ions does not increase proportionally with the addition of metal oxides to a silicate slag. Also a limited desulphurizing power of magnesia, compared to lime, can be expected, since the binding forces between magnesium and oxygen ions are greater than those between calcium and oxygen ions.<sup>17</sup> Hence,<sup>2</sup> the substitution of 1 mol of magnesia for 1 mol of lime in a slag would result in a decrease in the oxygen-ion concentration.

### Summary and Conclusions

This investigation has studied the influence of basicity and (FeO) content of the slag upon sulphur distribution between molten iron and slags of low (FeO) concentration. These slags are similar to those encountered in the electric furnace during the reducing stage. It has been possible to extrapolate the data obtained to the blast-furnace and to the open-hearth range, and the following conclusions have been reached.

1—Satisfactory correlations are found by computing the molar composition of the slags on the basis of a complete neutralization of the acids ( $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ ). Such a neutralization is assumed to require 2 mols of bases (CaO, MgO) per mol of acid for the more basic slags, and 1 mol of bases per mol of acids for the less basic slags. The boundary between the two methods of computation is found in a range

near the value of the basicity  $b = \frac{N_{\text{bases}}}{N_{\text{acids}}} = 2$ , and

in this range neither method of computation is entirely satisfactory.

2—Influence of FeO: For all FeO concentrations desulphurization can be explained on the basis of the following reactions:

$$K = \frac{a_{\text{FeO}} \cdot a_{\text{CaS}}}{a_{\text{CaO}} \cdot a_{\text{S}}} \quad [4]$$

In highly reduced slags [(FeO) < 2 pct] desulphurization is mainly controlled by reaction 2 and the desulphurization ratio increases rapidly with decreasing (FeO) content of the slag.

In slags containing higher amounts of (FeO) reaction 1 gradually acquires importance since the amount of sulphur combined with lime decreases rapidly as (FeO) increases. Finally, for higher

amounts of (FeO) in the slag (FeO > 10 pct), the sulphur combined with lime becomes a small fraction of total sulphur present in the slag, and reaction 1 is the predominant controlling factor. The desulphurization ratio, in this range, is approximately independent of the (FeO) concentration for slags of the basic open-hearth type.

3—Influence of CaO: For all slags containing less than 10 pct FeO the value of excess CaO computed by the method of Sherman and Grant<sup>8</sup> is also one controlling factor, and the desulphurization ratio increases with increasing amounts of excess CaO. Magnesia has little or no desulphurizing power in this range, its only effect being that of increasing the basicity of the slag.

# Vacuum Treatment of Parkes' Process Crusts On a Pilot-Plant Scale

by A. W. Schlechten and R. F. Doelling

**Parkes' process crusts were vacuum distilled using a shortened Pidgeon retort. Zinc was effectively removed below 800°C and recovered as a zinc sheet easily stripped from the furnace liner. Lead distillation required about 950°C and the resulting lead condensate tended to stick to the thin metal liner. Final purity of residue is limited only by nonvolatile metals such as copper.**

THE successful commercial application of vacuum distillation for the removal of zinc from lead, as described by W. T. Isbell,<sup>1</sup> raises the question of whether or not a similar method can be used for other metal separations. Preliminary laboratory experiments on the vacuum distillation of Parkes' crusts by one of the authors<sup>2</sup> gave such encouraging results that it was decided to make a series of tests with large scale equipment to determine the results that might be expected in plant operation. The pilot-plant test results are reported in this paper.

The great advantages of vacuum dezincing are its simplicity, the relatively low temperature of operation, and the fact that the zinc is recovered in the metallic state ready for use again in the desilverization of lead bullion. These same advantages and others would be realized from the vacuum distillation of the zinc-lead-silver crusts made in the Parkes' process. Zinc readily will distill over at temperatures of 800° to 900°C as contrasted with the 1200°C or more used in the Faber du Faur furnace. Furthermore, the recovery of zinc as metal is practically perfect since there is no loss by oxidation or fuming.

If the vacuum distillation is continued and hastened by raising the temperature to around 1000°C, the lead will distill over at an appreciable rate and deposit in a warmer zone of the condenser. This lead will contain a small amount of silver, but it can be returned to the desilverizing kettles and there is not the chance of loss that there is in disposing of the rich litharge from cupelling. The lower temperatures required will mean a saving of fuel and less wear on the equipment. One further point is that the vacuum distillation could be run

on a small scale practically continuously, so as to avoid the accumulation of large amounts of silver-rich material and the need of assembling a large crew for special cupellation runs.

It should be pointed out here that the final purity of the silver residue will depend on the copper or iron content of the crusts, as these and other metals with low vapor pressure will not be eliminated.

The idea of treating the silver-zinc-lead crusts from the desilverization of lead bullion by vacuum distillation is not a new one, but such experiments have not been reported, as far as can be determined. In 1912, T. Turner presented a paper<sup>3</sup> before the Institute of Metals on the vacuum distillation of brass, and a member of the audience suggested that he try his method on Parkes' crusts. In 1935, W. J. Kroll, noted for his discovery of debismuthizing lead by calcium additions, published a paper<sup>4</sup> on vacuum distillation of metals and pointed out possible applications in the lead industry.

## Principles of Separation

The successful separation of two or more metals by distillation depends upon an appreciable difference in the effective vapor pressures of the metals in the alloy to be treated. The vapor pressures of the common metals have been determined with considerable accuracy; for example, at 800°C the vapor pressures of the individual metals which are of particular interest in this paper are about as follows: Zn, 241 mm; Pb, 0.0553 mm; and Ag, 0.000276 mm.

Unfortunately, data are not available on the activities of the components in the ternary system Zn-Pb-Ag, but it can be estimated that on the basis of the vapor pressures of the individual metals a good separation can be made by distillation. The preliminary laboratory tests previously mentioned<sup>2</sup> supported this assumption.

The pilot-plant size vacuum distilling furnace is shown in Fig. 1. It consisted of an abbreviated Pidgeon retort, 5 ft long with an ID of 8 in., heated by six silicon carbide elements placed symmetrically

around and parallel to the retort. The temperature was measured by a chromel-alumel thermocouple peened to the outside of the retort under the charge.

The retort was connected directly to a 6-in. oil diffusion pump, Type 104, manufactured by the National Research Corp. The diffusion pump, in turn, was connected to single-stage mechanical vacuum pump, Type VSD 778, made by the Kinney Manufacturing Co. The details of temperature control and vacuum measurement can be seen from the figure. A boat to hold the charge was made of 1/16-in. sheet iron, and a 20-gage black iron sheet was inserted in the cold end of retort to serve as a liner on which the metal vapors could condense. A simple baffle in the connection between the retort and the diffusion pump effectively prevented the zinc vapors from entering the pump.

### Experimental Procedure

The experimental work was conducted to determine, first, the effect of time, temperature, pressure, and amount of charge on the quality of products obtained, and to determine, second, whether the operation could be carried out practically without too many difficulties.

In a typical run, the mechanical pump brought the pressure in the system down to 100 microns within 5 to 10 min at which time the diffusion pump was turned on. In an additional 20 min the diffusion pump reduced the pressure to the 10 to 30 micron range where most of the runs were made. The evacuation of the retort was accomplished so rapidly that the heating could be started at the same time as the pumps without fear of oxidizing the charge.

When the desired furnace temperature was reached, little attention was needed except for an occasional check on the pressure and the cooling jacket water. At the end of the heating cycle the furnace was turned off and the retort was allowed

to cool to about 200°C, then the pumps were stopped, and the retort was opened. In order to more nearly duplicate expected plant procedure, the above operations were hastened in Runs 20 and 21 by charging and discharging the retort when it was almost at operating temperature.

### Materials, Sampling, and Analytical Methods

The crusts used for experimentation were obtained from two different lead smelters; the composition of the crusts given in Table I are the mean of numerous analyses made on several samples. Crust No. 1 was a typical pressed crust although somewhat high in copper. Crust No. 2 was a liquated crust and was low in lead; the appreciable amount of iron was probably picked up from the liquating kettle.

The products of the furnace consisted of a condensate and a residue. The condensate could be roughly divided into a sheet, mainly zinc, which stripped easily from the liner and a high lead material from the hot end of the liner. The high lead material, which had condensed in the liquid state, consisted of small droplets and of larger masses which had run together and solidified.

The condition of the residue depended on the operating temperature. After runs of 800°C or less the residue was granular and broke up easily. If the temperature went above 800°C, partial fusion or even complete melting took place and the residue was in one solid piece.

### Experimental Results

The results of the various runs showed the effect of time, temperature, pressure, and size of charge on the completeness of distillation and the final composition of the residue. These results can be shown best graphically by grouping the data from a series of runs with but one variable.

*Effect of Time:* Figs. 2 and 3 show respectively the weight of the various metals in the residue after runs of varying time on Crust No. 1, the high lead crust, and Crust No. 2, the liquated crust; the tem-

Fig. 2—Weight of metals in residue from distillation of Crust No. 1 for various lengths of time.

Charge, 12,000 g; temperature, 900°C; pressure, 17 to 40 microns.

Table I. Composition of Crusts

| Number      | Zn, Pct | Pb, Pct | Ag, Pct | Fe, Pct | Cu, Pct | Total |
|-------------|---------|---------|---------|---------|---------|-------|
| Crust No. 1 | 54.45   | 33.79   | 9.45    | 0.70    | 2.00    | 99.69 |
| Crust No. 2 | 63.70   | 8.60    | 26.85   |         |         | 99.85 |

perature was the same and the pressure essentially the same for each group. Both graphs show the same pattern of the early and rapid elimination of practically all of the zinc accompanied by a slower, but steady, elimination of lead, and a very gradual loss of silver from the residue.

**Effect of Temperature:** Fig. 4 shows the weight of the various metals left in the residue of Crust No. 2 when the temperature is increased; the time and the amount of charge were the same and the pressure essentially the same in each run. The graph shows that the zinc is removed effectively at the lowest temperature used, but that the higher temperatures are needed for the removal of the lead if a time of 3 hr is used.

**Effect of Charging Hot Retort:** The time of the runs reported in the previous sections refer to the time at operating temperature; the time to bring the retort to temperature and to cool it was not included. This raises two questions: First, how much of the effective distillation takes place in the heating and cooling times, and second, can the retort be charged and discharged while hot without detrimental oxidation of the charge or the products? To settle these points, two runs were made in which the retort was charged at 800°C, sealed and pumped down, brought to 900°C, held for 3 hr, cooled to 850°C, and then opened. The products were removed immediately; the overall time was about 4 hr.

As can be seen from Fig. 5, the results are much the same as with the longer procedure. Only on the weight of lead left in the residue can it be seen that the distillation during the heating and cooling periods helps eliminate a slight amount more of metal. The elimination of zinc is so nearly complete in all instances that no difference can be detected, and the distillation of silver is so slight that no difference can be seen.

Certainly the hot charging had no detrimental effect that can be noticed and accomplished almost as much as the runs with the long heating and cooling periods.

Fig. 3—Weight of metals in residue from distillation of Crust No. 2 for various lengths of time.

Charge, 8854 g; temperature, 950°C; pressure, 17 to 32 microns.

Fig. 4—Weight of metals in residue from distillation of Crust No. 2 at various temperatures.

Charge, 8854 g; time, 3 hr; vacuum, 28 to 50 microns.

**Effect of Pressure:** The rate of distillation of all of the metals should be greater at lower residual pressures in the retort. The question arises as to whether the slightly greater rate of distillation warrants the use of pressures as low as 10 to 30 microns. These lower ranges almost require a diffusion pump in the circuit, if any speed of pumping is desired.

Several runs were made using only the mechanical pump so that pressures of 120 to 135 microns were measured. The results of these runs also are shown in Fig. 5 and again any difference is only apparent in the lead content. The amount of lead eliminated after 3 hr at 900°C is not quite as great at the higher pressures. However, this difference is so slight that a small increase in the time or temperature would overcome it. It would appear that there is no real advantage in using pressures less than 100 or 150 microns.

**Effect of Size of Charge:** The retort used for these experiments was only 5 ft long as compared with the 10 ft retorts used at some commercial magnesium plants. These commercial retorts could take a much larger charge, so it was desirable to know how the size of charge would affect the distillation. The results are shown in Table II.

Apparently the zinc is evaporated for the most part in the heating period before the charge becomes molten. Since in the solid state the surface area is a function of amount of charge, about the same

degree of zinc removal is obtained. The major portion of the lead, however, is evaporated after the temperature is above the melting point of the crust, and in this case the surface area is independent of amount of charge except with respect to the cross-section of the boat at various depths. The boat which was used apparently had a cross-section such that at the operating conditions about 2000 g of Pb could be evaporated in 3 hr. From these data then the optimum charge for the given conditions and the boat being used can be calculated.

**Loss of Silver to Condensate:** With the extended time and higher temperatures necessary for the distillation of lead, some silver will also be carried over into the condensate. This carry-over is not a true loss as the silver will be largely in the condensed zinc and lead which can be returned to the desilverizing kettles.

The distribution of the silver in the various products is shown in Fig. 6 and in Table III which records the results of a run in which both the lead and zinc were removed almost completely. The final purity of the residue was kept down by the excessive amount of copper in the original crusts. It can be

seen that the high-zinc sheet condensate contains about 3 pct of the total silver, while the high-lead granular products contain 4.7 pct of the total silver. The 12.8 pct Ag not accounted for in the analyses condensed in the hottest portion of the condenser as an alloy running about 80 pct Ag. For a single run there was not enough of this material to be recovered, but in practice this would build up to the extent that it could be recovered and ultimately there would be no loss.

The results given in Table III are from the treatment of a low grade crust; much more favorable results can be obtained with a liquated crust as shown in Table IV.

**Operating Conditions:** No difficulty was experienced in maintaining an adequate vacuum in the system or in operating the pumps or furnace. Charging the retort is simple, and the only problem lies in the removal of the products. As mentioned before, the high zinc sheet is easily stripped from the liner, but the high lead material tends to stick. In practice there would be no necessity of complete removal of the condensate and so the sticking would not be too serious.

The residue containing copper tends to stick in the charge boat and will attack a sheet iron boat in runs at a high temperature. It might be preferable, therefore, to make the boat of cast iron or of a ceramic material.

## Conclusions

- 1—Zinc is readily removed from Parkes' process crusts at low temperatures by vacuum distillation.
- 2—Lead can be removed by extended time and increased temperature.
- 3—The purity of the residue will depend upon the amount of nonvolatile metals in the residue. A liquated crust was distilled to yield a residue analyzing 95.7 pct Ag, 2.4 pct Fe, 1.7 pct Pb, and 0.2 pct Zn. This residue contained 96.9 pct of the silver in the charge.

# Constitution Of Iron-Chromium-Molybdenum Alloys At 1200°F

by Spencer R. Baen and Pol Duwez

**A**LTHOUGH the practical importance of Fe-Cr-Mo alloys has long been recognized, constitution studies have been limited to a few alloys within rather narrow ranges of composition. The purpose of the present study was to establish the phase boundaries in the ternary diagram at a temperature of 1200°F (650°C).\*

The identification of phases and the determination of phase boundaries were based primarily on X-ray diffraction measurements and occasionally on microscopic observation. The methods used for locating the phase boundaries were essentially those described in detail by Andersen and Jette,<sup>1</sup> and by others.<sup>2,3</sup> The compositions of 180 alloys, prepared by powder metallurgy techniques, are shown in Fig. 1. The chemical analysis and mesh size of the powders which were used for the preparation of the alloys are given in Table I.

The powders were mixed for 48 hr or longer, then compacted under 80,000 psi in a ½-in. diam steel die. Each specimen weighed approximately 5 g. The compacts were sintered for 4 hr at 2500°F (1371°C) in an atmosphere of pure dry hydrogen (dew point near the temperature of liquid nitrogen). An open tray of chromium powder was placed upstream of the compacts to act as a "getter" for the last traces of oxygen or water vapor. In many cases this chromium powder was bright after sintering. Occasionally the upstream side of the powder was slightly greenish, but in all cases the downstream side was metallic. Some of the alloys contracted during sintering and some expanded as much as 20 pct. The latter alloys, which in all cases were brittle, were crushed in a tool steel mortar, repressed, and resintered for 4 hr at 2500°F. After sintering, the alloys were aged for ten days at 1200°F (650°C) in evacuated (10<sup>-5</sup> mm Hg or better) fused silica tubes and were cooled rapidly to room temperature following the aging treatment.

\* After this study was completed, a paper on the same subject was published by Putman, Potter, and Grant.<sup>13</sup> These authors investigated the phase boundaries in the Fe-Cr-Mo ternary system at 900°, 1100°, and 1300°C. Duplication of effort was fortunately avoided and the combination of the two studies provides a good picture of the phase relationships in the ternary system at four temperature levels.

The use of the powder metallurgy technique in preparing alloys for structural investigation offers a simple method of avoiding contamination or non-homogeneity which could result from a melting operation. It is very often possible to dispense with chemical analysis of the alloys which have been prepared by the powder metallurgy method. In lieu of chemical analysis, it is necessary to determine the weight of the compact before and after sintering. The chemical composition of the alloy may be considered as that of the green compact, within the limits of accuracy determined by the loss of weight during sintering.

In phase-diagram studies it is important to achieve homogeneity in structure, whether the alloys are prepared by powder metallurgy or by melting. Homogeneity means complete diffusion during the sintering of the alloys which are prepared by powder metallurgy. It has been found from experience that the best criterion for establishing the completeness of diffusion is the sharpness of the X-ray diffraction patterns. This criterion has been used throughout the present study.

The X-ray diffraction data were obtained using powder cameras of either 214.86 or 71.62 mm diam. Copper, cobalt, or chromium K $\alpha$  radiation was used, the choice being based on the alloy composition. The powder samples were obtained by filing or crushing, depending on whether the alloy was ductile or brittle. In some cases, the powder was annealed for 4 to 6 hr at 1200°F in vacuum. The measurements were corrected for film shrinkage and absorption. The large camera, in which the film is mounted

SPENCER R. BAEN, Captain, U. S. Army Field Forces Board No. 2, Fort Knox, Ky., was formerly Graduate Student in Mechanical Engineering, California Institute of Technology. POL DUWEZ, Member AIME, is Associate Professor of Mechanical Engineering, California Institute of Technology, Pasadena.

Discussion of this paper, TP 3036E, may be sent (2 copies) to AIME by June 1, 1951. Manuscript, Oct. 13, 1950; revision, Jan. 25, 1951. St. Louis Meeting, February 1951.

This paper is based on a thesis by Captain Baen submitted in partial fulfillment of the requirements for the degree of Doctor of Philosophy to the California Institute of Technology, July 1950.

Fig. 1—Ternary diagram showing composition of alloys in atomic percentage.

symmetrically with respect to the X-ray beam, was calibrated with calcite. For the small camera, film shrinkage automatically was taken into account by mounting the film assymmetrically, the Straumanis technique. Absorption corrections were made following the graphical extrapolation method recently described by Nelson and Riley.<sup>4</sup> This technique was found more expeditious than the more generally used Cohen's method.

### Binary Systems

Although the three binary systems have been established previously, binary alloys were prepared in order to obtain additional X-ray diffraction data and to check the phase boundaries at 1200°F.

Phase boundaries which involve the  $\sigma$  phase in the Fe-Cr binary system have been located most reliably by Cook and Jones.<sup>5</sup> The present study confirmed their results by establishing from X-ray diffraction measurements that at 1200°F the  $\sigma$  phase extends from 43 to 50 atomic pct Cr. The end points of the two-phase regions were located near 30 and 71 atomic pct Cr. These results agree closely with those of Cook and Jones and furnish new evidence that the  $\sigma$  phase extends closer to both iron and chromium than was indicated by previous investigators, see, for example, ref. 6.

The generally accepted phase diagram for the Fe-

Mo system<sup>7</sup> is a compromise between the results obtained by Sykes<sup>8</sup> and by Takei and Murakami.<sup>9</sup> The most important points which have a bearing on the present work are the solubility limits at both ends of the diagram at 1200°F and the exact location of the  $\epsilon$  phase. The solubility of iron in molybdenum was determined by plotting the lattice parameter of alloys 43 through 50 vs. composition. The solubility limit was located at 8 atomic pct Fe. The same procedure applied to alloys 24 through 28 indicated that the solubility of molybdenum in iron is 4 atomic pct. These results confirm the location of the phase boundaries of the equilibrium diagram given in ref. 7.

The  $\epsilon$  phase of the Fe-Mo system has been located by Sykes<sup>8</sup> between 39 and 40 atomic pct Mo. The upper boundary corresponds to the formula  $\text{Fe}_3\text{Mo}_2$ . Arnfelt and Westgren<sup>10</sup> found the structure of this phase to be rhombohedral  $D_{3d}$  with  $a = 8.97 \text{ \AA}$  and  $\alpha = 30^\circ 38.6'$ . These investigators proposed the formula  $\text{Fe}_2\text{Mo}_3$  because this structure requires 13 atoms per cell. The rhombohedral structure of the  $\epsilon$  phase was confirmed by the present investigation for alloy 12, which has an  $\text{Fe}_3\text{Mo}_2$  composition. Alloy 13, which corresponds to  $\text{Fe}_2\text{Mo}_3$ , and alloy 14, which corresponds to  $\text{FeMo}$ , showed characteristic diffraction lines of the molybdenum-rich  $\alpha$  solid solution. Alloys 80 through 83 were examined and found to contain the  $\epsilon$  phase with the same parameters. The iron-rich solid solution was detected in alloys 83, 82, and 81, and microscopic investigation revealed that alloy 80 consisted of two phases. It was concluded that the  $\epsilon$  phase is located near the  $\text{Fe}_3\text{Mo}_2$  composition and extends less than 2 pct towards iron. The stoichiometric composition  $\text{Fe}_2\text{Mo}_3$ , which characterizes the crystal structure of  $\epsilon$ , is not inside the phase boundaries of the single-phase region. This anomaly has been found in several alloy systems.

The Cr-Mo system has been investigated by Trzebiatowski,<sup>11</sup> who showed that the two metals form an uninterrupted series of solid solutions. These results were confirmed and the variation of lattice parameter vs. composition is shown in Fig. 2. The small difference between the present results and those given by Trzebiatowski has no obvious explanation. The possible existence of a phase of the  $\sigma$  type or of an ordering reaction in the Cr-Mo system was investigated by heat treating the alloys for 6 weeks at 1200°F. The powder patterns obtained after this treatment indicated only the presence of the  $\alpha$  phase.

### Ternary System

The cross-section of the ternary-phase diagram at 1200°F is given in Fig. 3. The contours of equal lattice parameter in the  $\alpha$ -solid solution regions are labeled in A units. In the  $\sigma$ -phase region the parameter given in Fig. 3 is that of the smallest axis of the tetragonal cell of  $\sigma$ .† The ternary diagram is also presented in Fig. 4, in which the compositions are given in weight percentages. A few interesting details concerning the location of some of the phase boundaries are discussed below.

**Phase Boundaries of the  $\alpha + \sigma$  Region:** The phase boundaries of the  $\alpha + \sigma$  region were established by locating the intersection of the tie lines in this two-phase region with the lines of the constant lattice parameter in the  $\sigma$  and  $\alpha$  fields. The accuracy of a

† A tentative unit cell for the  $\sigma$  structure and a more detailed discussion of the  $\sigma$  field are given in ref. 12.

phase boundary which is determined by this method depends on the angle of intersection of the tie lines in the two-phase region with the parameter contours in a one-phase region. The best conditions are achieved when this angle is near  $90^\circ$ . In the particular case of the boundary between the  $\alpha$  and the  $\alpha + \sigma$  fields, see Fig. 3, the uncertainty in the position of the phase boundary is rather large for molybdenum concentration less than about 25 atomic pct, since in this region the parameter contours intersect at a small angle.

The X-ray diffraction patterns of the alloys which are located in the  $\alpha + \sigma$  field clearly revealed the presence of the two phases, with two exceptions. The  $\alpha$  phase was not observed in the diffraction patterns of alloys 105 and 20. However, microscopic observation confirmed the existence of the  $\alpha$  phase in these alloys. As an example, the structure of alloy 20 (40 pct Fe, 50 pct Cr, and 10 pct Mo) containing  $\alpha$  and  $\sigma$  phases is shown in Fig. 5a. The X-ray diffraction patterns of some of the two-phase alloys did not always reflect the correct proportions of  $\sigma$  and  $\alpha$ . For example, the intensity of the  $\sigma$  pattern of alloys 31, 21, and 37 was very weak, although the relative proportion of  $\sigma$  in these alloys, see Fig. 3, should be approximately 25, 50, and 75 pct, respectively. It is of course quite possible that the powder sample mounted in the camera did not contain the true proportion of  $\alpha$  and  $\sigma$ . Quantitative X-ray diffraction analysis is particularly difficult in the present case of a very brittle phase dispersed in a ductile matrix.

**Phase Boundaries of the  $\alpha + \epsilon$  and the  $\alpha + \epsilon + \sigma$  Fields:** The complicated diffraction pattern of  $\epsilon$  superimposed on the equally complicated pattern of  $\sigma$  presented a practical difficulty in interpreting the structure of several ternary alloys in a region of low chromium content. Where only a small proportion of  $\epsilon$  existed with a large proportion of  $\sigma$ , or vice versa, it was difficult to ascertain the presence of the minor constituent. For example,  $\sigma$  was not detected in alloys 153 and 154, and the presence of  $\epsilon$  was questionable in alloys 75 and 137. The proof that these alloys actually are located in a three-phase region was based on the invariancy of the lattice parameters of the two observed phases.

The boundary between the  $\alpha + \epsilon$  region and the  $\alpha + \epsilon + \sigma$  region was located parallel to the Mo-Fe side of the diagram and within less than 1 pct Cr, because alloys 156 and 164, which contain 1 atomic

Fig. 2—Lattice parameter vs. composition of Cr-Mo binary alloys.

Fig. 3—Phase boundaries in ternary Fe-Cr-Mo diagram at  $1200^\circ\text{F}$  ( $650^\circ\text{C}$ ). Compositions are in atomic percentages.

pct Cr, contained three phases. The intersection of this boundary and the parameter contour of 3.125 Å in the  $\alpha$  single-phase region established the  $\alpha$  apex of the  $\alpha + \epsilon + \sigma$  triangle. The lattice parameter of the  $\alpha$  phase in alloys which consisted of three phases was 3.125 Å.

The  $\epsilon$  apex of the  $\alpha + \epsilon + \sigma$  triangle was determined from the results obtained on a series of alloys which contained 2 atomic pct Cr (Nos. 151 through 155). Alloys 153, 154, and 155 contained three phases, while alloys 152 and 88 contained only two phases and were approximately on the same tie line in the  $\epsilon + \sigma$  region. From these results, the  $\epsilon$  apex was located at approximately 54 pct Fe, 45 pct Mo, and 1 pct Cr.

The boundary between the  $\alpha + \sigma$  region and the  $\alpha + \epsilon + \sigma$  region was established on the basis of the  $\alpha$  apex of the three-phase triangle and the nearest known tie line in the  $\alpha + \sigma$  region. The apex of the three-phase region was located so that it would fall on the correct lattice parameter contour of the one-phase  $\sigma$  region.

**Fe-Rich Corner:** In the Fe-rich corner of the ternary system, the X-ray diffraction method was supplemented by microscopy. In this region, it was difficult to determine accurate contour lines because of the small variation in lattice parameter with composition. Hence, the phase boundaries in the vicinity of the  $\alpha'$  apex of the  $\alpha' + \epsilon + \sigma$  region were located approximately from X-ray data, then a series of additional alloys, Nos. 168 through 185, were prepared for metallographic observation. The boundary between the  $\alpha'$  region and the  $\alpha' + \epsilon$  region was located between alloys 168 and 169, namely, between 1 and 2 pct Mo on the 10 pct Cr line. The structures of alloys 168 ( $\alpha'$ ) and 169 ( $\alpha' + \epsilon$ ) are shown in Fig. 5b and 5c. By the same method, the boundary between the  $\alpha' + \epsilon$  region and the  $\alpha' + \epsilon + \sigma$  region was found between alloys 174 and 175 and was traced as shown on Fig. 3. This boundary intersects the 10 pct Cr line near 9 pct Mo.

Alloys 178, 179, and 147 were used for the determination of the boundary between the  $\alpha' + \sigma$  region and the  $\alpha' + \epsilon + \sigma$  region. The structure of alloy 178 revealed three phases with the  $\epsilon$  phase distributed in a matrix of  $\alpha'$  and with the  $\sigma$  phase

Fig. 4—Phase boundaries in Fe-Cr-Mo ternary diagram at 1200°F (650°C). Compositions are in weight percentages.

at the grain boundaries. In alloy 179 the  $\sigma$  phase was precipitated at the grain boundaries. An X-ray diffraction pattern of alloy 147 showed very weak lines of the  $\sigma$  phase. As a result of these observations, the boundary between the  $\alpha' + \sigma$  region and the  $\alpha' + \sigma + \epsilon$  region was located near 6 pct Mo on the 80 pct Fe line.

A comparison of the structure of alloys 182 and 183 led to the conclusion that the boundary between the  $\alpha'$  region and the  $\alpha' + \sigma$  region passes through a point between 1 and 2 pct Mo on the 80 pct Fe line. The boundary between the  $\alpha' + \sigma$  region and the  $\sigma$  region was based on the structures of alloys 17, 18, 56, 97, 98, 100, and 148. The microstructure of all these alloys clearly indicated the presence of the two phases. The X-ray diffraction results confirmed the presence of the two phases, except for alloy 98 in which no body-centered phase ( $\alpha'$ ) was detected. The tie lines in the  $\alpha' + \sigma$  region were determined by the X-ray method. The boundary was drawn through the points of intersection of these lines with the parameter contours in the  $\sigma$ -phase field. It was then found that alloy 98 is very near the  $\sigma$  field and a cubic body-centered diffrac-

tion pattern was not observed because the amount of  $\alpha'$  was less than about 2 pct.

**Three-Phase Region  $\alpha' + \epsilon + \sigma$ :** As in the case of the  $\alpha + \epsilon + \sigma$  region, the simultaneous presence of  $\sigma$  and  $\epsilon$  caused some complications in analyzing the X-ray diffraction patterns of the three-phase alloys. The  $\epsilon$  pattern was present in all the alloys located in this field, except in alloy 91. The  $\alpha'$  phase also was observed clearly in all alloys, except No. 86. The invariance of lattice parameters was used as a further check for the three-phase alloy. The parameters of the  $\epsilon$  phase were very near that of the  $\epsilon$  phase in the binary Fe-Mo system; hence the  $\epsilon$  apex was located at 1 pct Cr.

The boundary between the  $\alpha' + \sigma$  region and the  $\alpha' + \epsilon + \sigma$  region was drawn through the 6 pct Mo, 80 pct Fe point, which was discussed above. This boundary was drawn with a slope such that it would include alloy 89 in the three-phase region and exclude alloy 56, which was a two-phase alloy ( $\alpha' + \sigma$ ). The end point of this boundary, the  $\sigma$  apex of the three-phase region, was determined on the basis of the parameter contours in the  $\sigma$  field and the parameter of the  $\sigma$  phase, which was present in the three-phase alloys.

The phase boundary between the two-phase region  $\epsilon + \sigma$  and the one-phase  $\sigma$  region was drawn as a smooth curve between the  $\sigma$  apexes of the two three-phase regions. The use of tie lines and parameter contours was not possible because of their near parallelism. Microscopic observation was also very difficult because the alloys which are located in this region were very porous and brittle. The location of the boundary, however, was substantiated by the observations that alloys 92 and 93 contained two phases, while alloys 74 and 79 contained only the  $\sigma$  phase.

**Accuracy in Location of Phase Boundaries:** Many different factors have an influence on the accuracy of the location of phase boundaries in a ternary system. The relative importance of the various sources of error change with alloy composition throughout the diagram. As a result, the overall accuracy in phase boundary determination varies from one region of the diagram to another, and it is practically impossible to make a definite statement about the width of the region of uncertainty associated with phase boundaries. In the present case, it is believed that the uncertainty does not

Fig. 5—Typical structures of three alloys.

a (left)—Alloy 20 ( $\alpha + \sigma$ ). b (center)—Alloy 168 ( $\alpha'$ ). c (right)—Alloy 169 ( $\alpha' + \epsilon$ ).

exceed 2 atomic pct and is probably not more than 1 pct in some regions of the diagram. These figures do not apply to part of the boundaries between  $\alpha$ ,  $\alpha + \sigma$ , and  $\sigma$  phases near the Fe-Cr side of the diagram. The uncertainty of these boundaries, which are dotted on Fig. 3, may be greater than 2 pct because some of the alloys in this region may not have reached equilibrium at 1200°F. The most logical method for improving the results in this region would be to make a study of the isothermal transformation of  $\alpha$  into  $\sigma$ , so that the attainment of equilibrium can be established definitely.

### Summary

The phase boundaries of the Fe-Cr-Mo ternary system have been determined at 1200°F (650°C). The method used for locating the phase boundaries consisted of measuring lattice parameters of the various phases and drawing the parameter contours and the tie lines in the one-phase and two-phase regions, respectively. The brittle  $\sigma$  and  $\epsilon$  phases extend over a major portion of the diagram. The largest one-phase solid solution region is located near the chromium corner of the diagram.

## Titanium-Boron Alloys

by H. R. Ogden and R. I. Jaffee

AT the present time, there appear to be two conflicting opinions on the solubility of boron in titanium. P. Ehrlich<sup>1</sup> has indicated from X-ray diffraction work that boron is soluble in titanium up to TiB<sub>0.8</sub> (17.8 wt pct, 44 atomic pct). The X-ray diffraction pattern for titanium was found in compositions up to TiB<sub>0.05-0.07</sub> (1.1 to 1.6 wt pct); then, without a phase gap, superlattice lines appeared up to TiB<sub>0.8</sub>. On the other hand, Craighead, Simmons, and Eastwood<sup>2</sup> have estimated the solubility of boron in both alpha and beta titanium to be less than 0.1 wt pct, based on results of metallographic analysis.

In some recent work done at Battelle, results were obtained which shed more light on the titanium-rich end of the titanium-boron system.

Iodide-type titanium and high-purity crystalline boron were used in this investigation. The boron was prepared by hydrogen reduction of boron tri-bromide and deposition on a hot tungsten wire. The

alloys were prepared by arc melting in an argon atmosphere of 10 cm Hg pressure on a water-cooled copper hearth. The ingots were hot rolled to strip at 850°C. Alloys containing up to 1 pct B could be hot rolled. Those containing 2 pct or more B could not be hot rolled.

Metallographically, it was found that a second phase was present in alloys containing as little as 0.4 pct B, and that the quantity of second phase increased with increasing boron content. This is illustrated in Figs. 1a and 1b, which show the microstructures of a Ti-0.4B and a Ti-1B alloy annealed in argon at 850°C.

X-ray diffraction patterns of alloys containing 1 and 5 pct B revealed the presence of extra lines which correspond to the superlattice lines reported by Ehrlich.<sup>1</sup> However, no evidence was found of a shift in the lattice constants of alpha titanium indicating that there is very little, if any, solubility of boron in alpha titanium. This fact, coupled with the fact that the alloys were definitely two-phase, indicates that the extra lines are not superlattice lines, but are more probably the result of a second phase of a hexagonal structure almost identical in cell

dimensions with that of alpha titanium. M. Hansen<sup>3</sup> has suggested that the titanium superlattice reported by Ehrlich may be a hexagonal-close-packed intermediate phase based on Ti<sub>2</sub>B. With this interpretation, the change in constants Ehrlich found for the hexagonal lattice would belong to the first titanium-rich intermediate phase, rather than the superlattice. Furthermore, it is known from Hagg's work, that in systems of metalloids and transition elements, M<sub>2</sub>X phases are usually hexagonal-close-packed.<sup>4</sup> This would account for the Ti<sub>2</sub>B structure in this system being hexagonal. Also, from the relative size of the interstitial elements, one would expect boron to have a lower solubility than carbon, which has been found to be about 0.5 wt pct maximum at the peritectoid temperature.<sup>5</sup>

Additional metallographic work has shown that boron additions do not measurably affect the transformation temperature of titanium. Figs. 1c and 1d show the structures of a Ti-0.4B alloy heated in argon and quenched in water from 880° and 893°C. At 880°C just below the 882°C transition temperature of titanium, the structure is alpha plus boride, while at 893°C, just above the transition of pure titanium, the structure is beta plus boride. This follows from the appearance of the alpha grains

after quenching. The transformation product of the beta phase consists of serrated Widmanstätten alpha plates, which are similar to those found in beta-quenched iodide titanium.<sup>5</sup>

The mechanical properties of the titanium-boron alloys used in this investigation also were obtained and are given in Table I. The addition of boron to titanium increases the strength only a moderate amount, but also decreases the ductility progressively. This is the type of effect that would be expected when a dispersed intermetallic phase is present in the structure.

It can be concluded from these data that the solubility of boron in both alpha and beta titanium is probably very low, well below 0.4 pct B, and that boron has no observable effect on the transition temperature of titanium. Furthermore, the hexagonal-close-packed structure of the second phase indicates that it is probably of the M<sub>2</sub>X type or Ti<sub>2</sub>B.

# Extraction of Alumina from Haiti and Jamaica Bauxites

by T. D. Tiemann

The chemical and mineralogical composition of Caribbean bauxite ores are described. Extraction of alumina by several processes from both Haiti and Jamaica bauxites is discussed and data presented.

IMMENSE deposits of bauxite occur in the Caribbean islands of Hispaniola and Jamaica in the high plateau lands and have been excellently described by O. C. Schmedeman.<sup>1</sup> The bauxite occurs as deposits in catchments or etched depressions in Tertiary limestone believed to have been deposited in the Eocene and Oligocene periods.<sup>2</sup> In appearance both the Haiti and Jamaica bauxites resemble a relatively high iron clay and have indeed been mistaken for such.<sup>3</sup> They are very soft and friable and disperse readily on vigorous agitation in water. The color range in general is light brown to red.

Chemically, the outstanding characteristic of the bauxites is the low silica and high ferric oxide content. The extremely low silica makes them particularly valuable for the production of alumina in the Bayer plant since silica is responsible for the loss of both alumina and soda chemically combined as  $XNa_2O \cdot YSiO_2 \cdot ZAl_2O_3$ . The ferric oxide, only traces of ferrous iron are present, offers no interference in the production of high grade alumina. Typical oxide analyses of three types of ore are given in Table I<sup>2</sup> and a list of the elements occurring in spectrographic quantities in Table II.<sup>3</sup>

The size of the individual particles in the ore makes successful petrographic examination extremely difficult. The ores contain some relatively coarse grains of heavy minerals such as ilmenite, magnetite, and rutile, but other than occasional crystals of a few microns, the greater portion of the minerals are submicroscopic in size and approach colloidal dimensions.

The mineralogic composition of the ores has been investigated by X-ray and differential thermal analysis.<sup>4</sup> These investigations indicate that the predominant mineral phases present are gibbsite ( $Al_2O_3 \cdot 3H_2O$ ), boehmite ( $Al_2O_3 \cdot H_2O$ ), hematite ( $Fe_2O_3$ ), and goethite ( $Fe_2O_3 \cdot H_2O$ ). There is no evidence of the occurrence of diaspore ( $Al_2O_3 \cdot H_2O$ ) in either the Haiti or Jamaica ores, but some type of "amorphous" alumina may be present in some of the bauxites of Jamaica.<sup>4</sup>

The temperature stability regions in the alumina-water system have been investigated and are given in recent literature. In the temperature range where the hydrated forms are stable, as determined by

hydrothermal bomb methods,<sup>5</sup> gibbsite is the stable phase to 155°C (311°F), boehmite from 155°C (311°F) to 280°C (536°F), and diaspore from 280°C (536°F) to 450°C (842°F).

Although quite similar in many characteristics, the Haiti and Jamaica ore show a divergence in mineralogic composition that is reflected in the extractability of the alumina described in later paragraphs. Two principal differences occur in mineralogic composition. The iron-bearing mineral in the Haiti ores is predominantly hematite, while in the Jamaica ores goethite is predominant.<sup>4</sup> Directly related to the extraction of alumina are the two minerals, gibbsite and boehmite. Boehmite is relatively high in the Haiti ores and in some of the less soluble Jamaica ores, while gibbsite predominates in the ores in Jamaica amenable to the American Bayer process of extraction.

## Pedersen and Related Processes

In general, all processes for the extraction of alumina involving sintering or fusion of bauxite ores with limestone, soda ash, or a combination of limestone and soda ash followed by leaching, are based on the formation of alumina compounds that yield alumina soluble in the subsequent leach.

The principal idealized reactions in respect to alumina and silica for the three types of processes are as follows:

### Soda Ash

#### Sinter:

#### Leach (with excess water):

### Soda Ash — Limestone

#### Sinter:

#### Leach (with excess water):

These latter reactions are the basis of the sinter process currently used for the recovery of soda and

alumina from the mud residues of the Bayer circuit.

#### Limestone

Sinter (modified Pedersen):

Leach (with excess water):

It will be noted that in the reaction with soda ash and limestone, the principal function of lime is to combine with the silica, thus liberating both alumina and soda which would otherwise be lost in the relatively insoluble sodium aluminum silicate; further, the combination of lime with silica decreases the silica taken into solution in the leach.

The original Pedersen process is based on the electrothermal fusion and simultaneous reduction of the iron oxide in the ore with coke to form as products metallic iron and a high alumina slag which is subsequently leached. The reactions in respect to calcium carbonate, alumina, and silica are, however, as indicated above.

In the Pedersen processes, formation of dicalcium silicate serves a dual purpose. The extraction of silica in the leach is lowered, and, if the compound composition and conditions of burning and cooling are correctly controlled, the beta-dicalcium silicate

formed at the high burning temperature (1200° to 1400°C) inverts on cooling to the gamma phase stable below 675°C.<sup>6</sup> This inversion takes place with a 10 pct increase in volume<sup>6</sup> which disintegrates the sinter or fusion, eliminating the necessity of grinding before the leach. This inversion causes the well-known "dusting" of the Portland cement industry.

In all of these types of treatment, the alumina is recovered from solution by precipitation with carbon dioxide liberated in the sintering stage. The sodium carbonate thus formed is recycled.

The silica content of the filtrate from the leach is considerably higher than in the Bayer processes, and usually some means of desilication must be employed preceding the precipitation of alumina.

Detailed descriptions of these processes are to be found in the literature. A rather complete description is given in a paper<sup>7</sup> on the application of the sinter methods to the treatment of clays.

*Application to Haiti Ores:* A rather extensive series of laboratory tests was made during the early investigation on Haiti bauxites to determine the possibility of applying these methods to the extraction of alumina. The greater part of the investigation was devoted to Pedersen treatment by both sintering and fusion methods.

Furnace treatment covered a temperature range of 1000° to 1500°C under both oxidizing and reducing conditions. The compositions in respect to CaO, Al<sub>2</sub>O<sub>3</sub>, and SiO<sub>2</sub> covered the greater part of the CaO-SiO<sub>2</sub>-Al<sub>2</sub>O<sub>3</sub> equilibrium diagram below 15 pct SiO<sub>2</sub>, ranging in CaO from 20 to 65 pct. Quenching in air or water as well as slow cooling was used.

Leaching conditions were investigated over a wide range in respect to concentrations, time, and temperature, and it was found that a leach of 30 min at 50°C using a 3 pct sodium carbonate solution in the ratio of one liter of solution to 25 g of sinter gave the most consistent results.

Although over 300 separate burns were made, the phenomenon of "dusting" was observed in only a few cases even with addition of silica.

Extractions\* of alumina were very inconsistent and in most cases were below 60 pct. Some extractions of 95 pct or greater were obtained, but these only under highly reducing conditions and at temperatures around 1300° to 1400°C. No quantitative relationship between composition with respect to CaO and extraction could be established. The very few cases of "dusting" encountered may have been due to the small amount of beta-dicalcium silicate formed in the low silica burns. However, in the burns made with the addition of silica, petrographic examination showed the presence of considerable beta-dicalcium silicate. It is known<sup>6</sup> that small amounts of oxides, among which may be mentioned B<sub>2</sub>O<sub>3</sub>, P<sub>2</sub>O<sub>5</sub>, V<sub>2</sub>O<sub>5</sub>, Cr<sub>2</sub>O<sub>3</sub>, in solid solution in the dicalcium silicate may prevent the beta to gamma inversion. This may be in part the reason for the apparent stability of the beta phase in the high silica tests.

A reaction not shown in the former discussion on sinter and fusion processes is that of CaO, Fe<sub>2</sub>O<sub>3</sub>, and Al<sub>2</sub>O<sub>3</sub>. These three oxides in the CaO-Al<sub>2</sub>O<sub>3</sub>-SiO<sub>2</sub>-Fe<sub>2</sub>O<sub>3</sub> system may combine to form tetracalcium aluminoferrite (4CaO·Al<sub>2</sub>O<sub>3</sub>·Fe<sub>2</sub>O<sub>3</sub>), a compound that is of common occurrence in both Port-

\* The term "extraction" as used throughout the discussion refers to results of laboratory tests. Actual plant recoveries of metal-grade alumina are estimated to be about 95 pct of the laboratory extractions.

Table III. Extraction vs. Digestion Time of Jamaica Bauxite of High Alumina Solubility

| Time, Min | Alumina Extraction, Pct |
|-----------|-------------------------|
| 15        | 97                      |
| 30        | 96                      |
| 60        | 96                      |

land and high alumina cements. If this compound formed, each mol of  $\text{Fe}_2\text{O}_3$  would combine with a mol of  $\text{Al}_2\text{O}_3$  and since these bauxites contain on the order of 20 pct  $\text{Fe}_2\text{O}_3$  and 48 pct  $\text{Al}_2\text{O}_3$ , approximately 27 pct of the alumina content would be lost in the extraction residue, allowing a maximum extraction of alumina of only 73 pct.

Consequently, with bauxite low in silica and high in ferric oxide, extraction of alumina may be low. An increase in extraction may result under reducing conditions where a substantial portion of  $\text{Fe}_2\text{O}_3$  is converted to  $\text{FeO}$ , or as in the original Pedersen fusion process converted to metallic iron. Application of the Pedersen processes to the treatment of these bauxites is felt to be entirely unsatisfactory from both technical and economic considerations.

Treatment by the soda ash and soda ash-lime-stone processes was also investigated.

High extractions of both soda and alumina (95 pct) were consistently obtained by sintering around  $1200^\circ\text{C}$ , followed by leaching for 30 min in water (100 g of sinter per liter) at  $50^\circ\text{C}$ . Solutions and alumina obtained from these tests were relatively high in silica content, indicating the need of a desilication step in a process employing these methods.

This type of extraction, though technically feasible, is doubtful from an economic standpoint as compared to treatment of these Haiti bauxites by a modified European Bayer process to be described.

### Bayer Processes

The principle of the Bayer process is based on the change in solubility of alumina in caustic solutions with variation in temperature. The solution, \*\* which is saturated with respect to alumina at digestion temperature, becomes supersaturated on subsequent cooling and precipitates alumina to the lower more stable concentration of the precipitation temperature. Precipitation is initiated by "seeding" with nuclei of alumina trihydrate.

These concentration levels are usually defined by the weight ratio of alumina in solution to caustic in solution expressed as free soda.† In normal plant operation, the lower stable concentration at precipitation temperature is represented by a ratio of about 0.30, while the ratio corresponding to the supersaturated level is around 0.57 to 0.58. Thus the weight of alumina produced per unit volume is represented by the difference of the two ratios or about 0.28 times the free soda concentrations. Decrease in the upper ratio represents decrease in production or a larger capacity requirement for the same production.

Although under special laboratory conditions high supersaturation can be attained, a limit corresponding to a ratio of around 0.60 is imposed in plant operation due to the danger of spontaneous precipitation on cooling from digestion temperatures.

The American Bayer process employs digestion temperatures in the region of  $290^\circ\text{F}$  and caustic concentrations of about 140 g per liter free soda while in the European Bayer process digestion temperatures as high as  $350^\circ\text{F}$  and caustic concentrations as high as 600 g per liter free soda may be

Table IV. Alumina Extraction vs. Digestion Temperature and Caustic Concentration of Jamaica Bauxite of Intermediate Alumina Solubility

used. An excellent discussion of this and other processes is given by R. S. Sherwin.<sup>8</sup>

*Application to Haiti and Jamaica Bauxites:* Under the mineralogic composition of these bauxites was mentioned a relation between the extraction of alumina and the relative mineral content of gibbsite and boehmite. The ores in Jamaica vary from a type high in gibbsite, from which the alumina is readily extracted, to ores containing mixtures of gibbsite and boehmite requiring higher temperatures and caustic concentrations to obtain suitable alumina recovery.

The Haiti bauxites are essentially of this latter type and require conditions of digestion approaching those of European Bayer practice, which in this paper is termed Modified European Bayer. No Jamaica ores examined so far in this laboratory have been found in which the alumina is as insoluble as that in the Haiti ores.

*Jamaica Bauxite of High Alumina Solubility:* Investigation of the digestion characteristics of the Jamaica ores has delineated an extremely large tonnage that is readily amenable to treatment under American Bayer conditions of digestion temperature and caustic concentration. It is to be noted that this type in general shows a loss on ignition of 27 pct or greater.

Loss on ignition in itself, however, is not the final criterion of alumina solubility since it may be related in part to organic content and hydration of minerals other than those of alumina.

This bauxite consistently gives extractions of 95 pct or higher of the total alumina content at saturation ratios (alumina:free soda) of 0.58 to 0.60. This amounts to almost complete extraction of the so-called available alumina‡ (theoretical maximum extractable alumina), and hence no increase in either temperature or caustic concentration will yield substantially higher alumina extractions.

It is perhaps advisable at this point in the discussion to mention the important fact that grinding is unnecessary to high yields of alumina due to the extremely fine size of the bauxite particles.

Closely related to the state of subdivision is the relation of time of digestion to alumina extraction. Many tests have indicated that time is not an important factor as far as alumina solubility is concerned and under any given conditions of tempera-

\*\* The term "solution" as used here includes colloidal as well as ionic and molecular solution.

† Free soda is equivalent to sodium hydroxide expressed as sodium carbonate. Thus 140 g per liter free soda  $\approx$  106 g per liter NaOH.

‡ Calculated available alumina is equal to the alumina in the bauxite less  $1.2 \times \text{SiO}_2$  content.

Table V. Extraction vs. Discharge Ratios, Haiti Bauxite

| Discharge Ratio,<br>Al <sub>2</sub> O <sub>3</sub> :Free Soda | Alumina<br>Extraction,<br>Pct |
|---------------------------------------------------------------|-------------------------------|
| 0.38                                                          | 72                            |
| 0.44                                                          | 63                            |
| 0.52                                                          | 61                            |
| 0.55                                                          | 56                            |
| 0.57                                                          | 17                            |

Digestion Temperature, 290°; Free Soda, 140 g per liter

ture and caustic concentration, the rate of solubility is relatively rapid. However, in normal plant practice, a period of at least 30 min is considered necessary for proper desilication. These relations are illustrated in the data of Table III which show the extraction of alumina relative to the time of digestion for these bauxites. The temperature for these data was 290°F and the caustic concentration 140 g per liter free soda.

**Jamaica Bauxite of Intermediate Alumina Solubility:** A large part of the Jamaica bauxites have been found to be somewhat less amenable to alumina extraction than the type previously discussed. These ores might be considered to be on the economic borderline of American Bayer practice. This ore quite generally shows a loss on ignition of around 25 to 26 pct and gives a total alumina extraction of 80 pct at saturation ratios of approximately 0.56 under American Bayer conditions.

The effect of digestion temperature as well as caustic concentration on this type of bauxite is illustrated in Table IV. In these particular tests, 93 pct extraction of total alumina represents 97 pct based on the calculated available alumina. It is interesting that neither increase in temperature nor increase in caustic concentration alone has an appreciable effect on the alumina extraction and that a change in both is required for a noticeable effect. This results in a relatively long flat portion of the extraction-temperature or extraction-caustic concentration curves parallel to the temperature or caustic concentration axis.

The cause of this has not been determined, but it may be in part related to an inversion of one min-

Table VI. Extraction vs. Temperature and Caustic Concentration, Haiti Bauxite

eral form to another with an accompanying decrease in solubility. It is to be noted that the inversion of gibbsite to boehmite takes place at 155°C (311°F), at least in the alumina-water system. This type of ore might be considered amenable to American Bayer practice if recoveries of around 80 pct were economically acceptable. However, it is probable that this ore could be more economically processed under the conditions of the Modified European Bayer processes described below.

**Jamaica Bauxite of Low Alumina Solubility:** A few of the Jamaica bauxites investigated were found to be quite unsuitable for treatment by the American Bayer process. These ores usually show a loss on ignition of about 20 pct and give an alumina extraction of 60 pct (0.56 ratio) under American Bayer conditions.

No detailed discussion or data for this type of Jamaica ore are presented since their behavior in respect to alumina extraction is quite similar to that of the Haiti ores discussed below.

Table VII. Extraction vs. Discharge Ratios Under Modified European Bayer Conditions for Haiti Bauxite

| Discharge Ratio,<br>Al <sub>2</sub> O <sub>3</sub> :Free Soda | Alumina Extraction,<br>Pct of:       |                                                     |
|---------------------------------------------------------------|--------------------------------------|-----------------------------------------------------|
|                                                               | Total Al <sub>2</sub> O <sub>3</sub> | Calculated Available Al <sub>2</sub> O <sub>3</sub> |
| 0.40                                                          | 96                                   | 100                                                 |
| 0.60                                                          | 93                                   | 98                                                  |
| 0.62                                                          | 89                                   | 94                                                  |
| 0.64                                                          | 63                                   | 67                                                  |

**Haiti Bauxite of Low Alumina Solubility:** In comparison with the first two types of Jamaica ores already discussed, the Haiti bauxites are somewhat unique with regard to alumina extraction. These bauxites are not at all amenable to American Bayer conditions, primarily due to the higher content of boehmite and in part to the higher silica. It will be noted from the analysis in Table I that these bauxites are typified by considerably lower loss on ignition (22 pct) than that of the former types and that the silica content is of the order of 3 to 4 pct.

American Bayer extractions are very low (60 pct), and the amount of alumina which can be carried in solution in respect to the caustic concentration is entirely unsuitable, never approaching a satisfactory ratio. An attempt to increase the ratio by increasing the bauxite causes a rapid decrease in extraction. This is illustrated in Table V. These considerations show why the Haiti ores cannot be economically treated by the American Bayer process.

However, the Haiti bauxites are extremely responsive to variation in temperature and caustic concentration. These relationships are illustrated in Table VI, which shows extraction vs. temperature at several caustic concentrations.

The extractions shown in Table VI are based on total alumina, and for this particular ore 92 pct represents 100 pct extraction of the theoretical calculated available alumina.

Investigations both in the laboratory and pilot plant, in which many samples of the Haiti orebodies were tested, have indicated that the most suitable digestion conditions for economic extraction of the alumina are in the higher temperature range and higher caustic concentrations somewhat below that of European practice. These conditions will yield

an extraction of approximately 90 pct of the total alumina or approximately 95 pct of the theoretical calculated available alumina based on an average analysis for these ores.

Shown in Table VII are the extraction characteristics under these Modified European Bayer conditions of an orebody typical of the Haiti deposits.

The few Jamaica ores similar to the Haiti ores in respect to composition and extraction characteristics, as well as the Jamaica ores of intermediate alumina solubility, give results comparable to those presented in Table VII when treated by the Modified European process.

No attempt will be made to introduce in this paper a detailed discussion of the settling and thickening of the residual red muds from Haiti and Jamaica bauxites resulting in the extraction of alumina from these bauxites. Laboratory tests have shown the muds to be readily flocculated by the use of starch as in current practice, and an investigation on pilot plant scale has shown that the settling and thickening characteristics are suitable for the thickener treatment.<sup>9</sup>

### Summary and Conclusions

Alumina is economically extractable from both Haiti and Jamaica bauxite by the Bayer process. A major part of the Jamaica orebodies are suitable for American Bayer treatment.

The Haiti bauxites and some of the Jamaica bauxites are amenable to treatment by a modification of the European Bayer process at high digestion temperatures and high caustic concentrations.

It is doubtful that either the Haiti or Jamaica ores can be economically treated by any of the soda or soda-lime sintering processes. The Pedersen sinter or fusion process is not suitable to treatment of bauxites of this type.

Variations in the extractability of the alumina

from both the Haiti and Jamaica ores are related principally to the relative amounts of boehmite and gibbsite present in the bauxites.

### Acknowledgments

The author thanks R. S. Sherwin and R. S. Sherwin, Jr., for their help and suggestions in preparing this paper. Thanks are due the staff of the Research Laboratory for their cooperation in supplying much of the data.

Where not otherwise noted, the data submitted are based on investigations made by the Alumina Research Department, Reynolds Metals Co., Listerhill Plant.

### Technical Note

## Structure of the Yellow Crystalline Fraction of Blast-Furnace Salamander

by John R. Weeks, Dan McLachlan, Jr., and John R. Lewis

**D**URING the operation of the iron blast furnace, aggregates of hard, infusible, yellow, cubic crystals frequently form in the interstices of the lining and on the hearth of the furnace. These were first examined by Wohler<sup>1</sup> and were identified by him as a complex cyanonitride of titanium, having a formula  $\text{Ti}(\text{CN})_2 \cdot 3\text{Ti}_3\text{N}_2$ , or more simply  $\text{Ti}_{10}\text{C}_2\text{N}_8$ . However, recent investigators have suggested that this complex compound does not exist. Recent work by Hume-Rothery, Raynor, and Little<sup>2</sup> on the carbide and nitride particles in titanium steels suggests that a complete series of solid solutions of the general

type  $\text{Ti}_{(10-y)}\text{C}_y\text{N}_8$  exists between titanium carbide (TiC) and titanium nitride (TiN). Assuming this to be true, it seems likely that Wohler's cyanonitride of titanium is in reality a solid solution of 20 mol pct TiC in 80 mol pct TiN, the nearly consistent carbide-to-nitride ratio probably resulting from temperature and pressure conditions in the blast furnace. The object of the present work was to investigate thoroughly this possibility of a solid solution by using the single-crystal methods of X-ray analysis.

A spectrographic qualitative analysis of a sample of the yellow crystals furnished by the Geneva Steel Co. showed, in addition to the titanium, strong lines of vanadium and moderate to weak lines of iron, magnesium, silicon, aluminum, and calcium. The last five were probably slag impurities, but the vanadium was possibly included in the yellow crystals, owing to a great structural similarity of its carbide (VC) and its nitride (VN) to the titanium compounds, Table II. A chemical analysis was made

Fig. 1b (right)—Drawing of the calculated unit cell of the yellow crystals.

of the sample for titanium, vanadium, carbon, and nitrogen. The results are shown in Table I. These show the ratio titanium plus vanadium to carbon plus nitrogen of 1 to 1.013 and indicate strongly the substitution of vanadium for titanium in the yellow crystals. Although the nearest empirical chemical formula based on Table I  $[(\text{Ti}, \text{V})_{11}\text{C}_2\text{N}_8]$  appears to be sufficiently close to the formula of Wohler ( $\text{Ti}_{10}\text{C}_2\text{N}_8$ ) to identify positively the substance examined with his "cyanonitride," yet it is sufficiently different from it to suggest that such a substance does not exist as a definite chemical compound.

A powder X-ray photograph of the sample used for the chemical analyses showed a simple diffraction pattern of the general type produced by sodium chloride. The lines were broad and diffuse, in some cases as wide as  $\frac{3}{4}$  mm, suggesting a mixture of a series of solid solutions in the sample. The best average cell dimension was chosen as  $a = 4.242\text{Å}$  and was obtained from a series of pictures using several different radiations. Table II shows this value as compared with published values of the cell dimensions for related compounds. It is seen to fall between the results determined for TiC and TiN by Hume-Rothery and associates, perhaps the most accurate values, and to lie appreciably nearer the value for titanium nitride. This cell dimension value, combined with the apparent structure ob-

tained from the general diffraction pattern of the powder, indicates strongly that the yellow crystals are primarily a solid solution of one part carbide in 4.7 parts nitride. For additional proof, the space group and structure were determined from a single crystal. The crystal used was a splinter from one of the large but extremely fragile cubes prominent in the sample. It was found to be cubic,  $a = 4.24\text{Å}$ , having  $\text{O}_h^s$  space group. (The single crystal was thus identified with the powdered sample of which the chemical analysis was known.) The intensities of the spots on the zero layer Weissenberg photograph were measured by visual comparison with standard intensity strips. The measured intensities were compared with those calculated for a sodium chloride type structure of titanium nitride and found to check well within the limits of the method of visual measurement. A Fourier projection of the electronic density,  $\rho(x, y)$  was obtained from the measured zero layer structure factors by using Bragg-Huggins masks<sup>5</sup> on a multiple projector. A photograph of the image obtained is shown in Fig. 1a. This shows peaks at all the assumed positions of atoms. It also clearly indicates all spots to be of equal intensity as would be predicted for an end view projection of the assumed structure shown in Fig. 1b. Therefore, it seems apparent that no complex cyanonitride of titanium exists in the yellow crystals found in the iron blast-furnace residues upon cooling.

### Acknowledgments

Thanks are due to the University of Utah Research Committee for their grant of a graduate research fellowship; thanks are also due to H. R. Bradford and W. J. Savournin of the Utah Engineering Experiment Station for their assistance in the chemical analysis.

Several weeks after completion of the present work, the authors were informed through private communications with Frank Fair, Claude R. Hudgens, and G. L. Clark that some work was then in progress on this subject at the University of Illinois. Upon receiving a preliminary draft of this article, they replied that their results, so far as they had proceeded, checked those obtained by the authors.

# Effect of Alloying Elements on True-Stress True-Strain Flow Curves of Pearlitic Steel

by R. Raring, J. A. Rinebolt, and W. J. Harris, Jr.

The effects of additions of alloying elements on the true-stress, true-strain characteristics of 0.30 pct C, 1.00 pct Mn, 0.30 pct Si pearlitic steel were studied. The alloying elements investigated were C, Mn, Si, P, Ni, Cu, V, Mo, Cr, Al, B, S, and Ti. The alloys are compared on the basis of fracture stress, fracture strain, energy to fracture, rate of strain hardening, strain hardening exponent, height of the flow curve, and lower yield point.

IN the past, nearly all studies of the effects of alloying elements on the tensile properties of metals have compared the conventional engineering parameters, namely, tensile strength, yield strength, elongation, and reduction of area. Recently, however, the true-stress, true-strain method of recording results from the tension test has been used; Lacy and Gensamer,<sup>1</sup> Hollomon,<sup>2</sup> and French and Hibbard<sup>3</sup> have used this method to study the effects of composition on strength and ductility of metals. In this paper, the effects of certain alloying elements on true-stress, true-strain curves of steels with nearly constant grain size and pearlite spacing are presented. The notation employed in this paper is given in Table I.

Since the definitions of stress and strain and the analytical geometry of the stress-strain curve have been explained previously, for example by Gensamer,<sup>4</sup> they will not be reviewed here.

However, the method used for the determination of energy to fracture,  $E_f$ , requires mention. These energy values were calculated on the assumption that the flow curve followed the idealized equation:<sup>4</sup>

$$\sigma = \sigma_{0.2} (\delta/0.2)^n$$

and the energy was taken as:

$$E_f = \int_0^{\delta_f} \sigma d\delta = \frac{\sigma_{0.2} \delta_f^{n+1}}{0.2^n (n+1)} \quad [1]$$

This integral was evaluated from  $\delta = 0$  to  $\delta_f$  to obtain the energy absorbed to fracture,  $E_f$ . MacGregor and Fisher have shown<sup>5</sup> that the area under the true-stress, true-strain curve to any strain value

Fig. 1—Experimental stress-strain curve and idealized curve from power law  $\sigma = \sigma_{0.2} (\delta/0.2)^n$ .

corresponds to the specific energy absorption to that strain value.

There is justification for preferring the use of eq 1 for the determination of the energy to a particular strain rather than the area under the experimental stress-strain curve, since Gensamer showed<sup>4</sup> that the use of the Bridgman correction<sup>6</sup> for stress at the neck of a tensile specimen brought the corrected experimental curve nearer to the idealized power-law curve than to the uncorrected experimental curve. However, it should be noted that the difference between the areas under the idealized curve and the experimental curve is not great for strain of less than 1.0, as can be seen from Fig. 1. In this figure, the true-stress, true-strain curve for a 0.01 pct C, 1.00 pct Mn steel is plotted through the experimental data points. From the value of  $\sigma_{0.2}$  from this curve and the value of  $n$  as determined by the  $\ln\sigma$ -

Table I. Nomenclature

|                             |                                                                                     |
|-----------------------------|-------------------------------------------------------------------------------------|
| $\sigma$                    | = true-stress                                                                       |
| $\delta$                    | = true-strain                                                                       |
| $\sigma_t$                  | = true-stress at $\delta = 0$ (extrapolated from the straight portion of the curve) |
| $\sigma_{0.2}$              | = true-stress at $\delta = 0.2$                                                     |
| $\sigma_f$                  | = true-stress at fracture                                                           |
| $n$                         | = slope of the $\ln\sigma$ - $\ln\delta$ plot (strain hardening exponent)           |
| $\delta_f$                  | = true-strain at fracture                                                           |
| $E_f$                       | = energy to fracture                                                                |
| $\Delta\sigma/\Delta\delta$ | = rate of strain hardening                                                          |

R. RARING, J. A. RINEBOLT, and W. J. HARRIS, JR., Member AIME, are associated with the Ferrous Alloys Branch, Metallurgy Div., Naval Research Laboratory, Washington.

Discussion of this paper, TP 3051E, may be sent, 2 copies, to AIME by July 1, 1951. Manuscript, Oct. 19, 1950; revision, March 7, 1951. St. Louis Meeting, February 1951.

ln $\delta$  plot of the same data, the idealized curve of the power law  $\sigma = \sigma_{0.2} (\delta/0.2)^n$  is also drawn. It can be seen that the experimental curve begins to deviate from the power law at about  $\delta = 0.4$  and the difference between the areas under the two curves to  $\delta = 1.0$  is only about 3 pct. Since most of the steels used in this investigation fractured at strains of less than 1.0, there should not be a great difference between the two areas. It is recognized that the use of the idealized equation for the calculation of  $E_f$  contains an element of inconsistency in that it results, in effect, in an adjustment in  $\sigma_f$  but not  $\delta_f$ . This objection could not be avoided, however, because of the lack of a method of adjusting  $\delta_f$  for the stress state existing at the neck of the specimen.

Material

The steels used in this investigation were made primarily for an investigation of the effects of composition on ductility in the notch-bar impact test; results of these notch-bar tests are reported by Rinebolt and Harris.<sup>7</sup> Since full particulars as to melting, deoxidation, forging, heat-treatment, metallographic and dilatometric techniques, and/or results are contained in ref. 7, they will be but briefly summarized here.

The steels were aluminum-killed; compositions were varied from a base analysis of 0.30 pct C, 1.00 pct Mn, 0.30 pct Si by splitting 250-lb laboratory melts. The final heat treatment was a controlled cooling from 1650° to 800°F at a rate of approximately 25°F per min and then slow cooling from 800°F to room temperature. Dilatometric tests<sup>7</sup>

Fig. 2—Variation of strength and ductility parameters with carbon content.

The vertical lines represent the value of four times the standard deviation of the property in 40 tests of 20 different base analysis heats.

showed that this treatment would result in essentially the same difference for all the steels, between the beginning of transformation on heating and the end of transformation on cooling. Since Pellissier,

Hawkes, Johnson, and Mehl have shown<sup>8</sup> that pearlite spacing is dependent on the difference between the critical temperature and the transformation temperature, all the steels should have very similar pearlite spacing characteristics. No absolute measurements of pearlite spacing were attempted, but several of the lowest and highest alloys of the series were compared by the resolution method<sup>8</sup> and no difference in pearlite spacing could be discerned.

The percentage of pearlite in all alloys was determined with a Hurlbut counter,<sup>9</sup> but no simple relationship between the absolute amount of pearlite and tensile properties was found. No attempts were made to study alloy partition between ferrite and carbide. Ferrite grain size was determined by comparing the structures at X100 with an ASTM grain size chart.

Certain alloy series which appear in the notch-bar impact report<sup>7</sup> were tested in tension, but data from only the Mo series are reported in the present paper because the tensile properties of these series of steels did not differ from those of the base analysis by significant amounts. These series, and the range of the alloying element studied were: Al series—0 to 0.09 pct Al; B series—0 to 0.004 pct B; S series—0.007 to 0.137 pct S; Ti series—0 to 0.39 pct Ti; and Mo series—0 to 0.29 pct Mo.

### Tensile Tests

Threaded-end, 0.357-in. diam tensile specimens with a 1.4-in. gage length were used. An automatic stress-strain recorder was used to measure strains to just beyond the yield point. The strain from the yield point to the fracture point was determined by measuring the minimum diameter of the specimen with pointed micrometers. All tests were made in duplicate and at room temperatures.

The stress-strain data were plotted on Cartesian and on logarithmic coordinates, and the rate of strain hardening,  $\Delta\sigma/\Delta\delta$ , and the value of the strain hardening exponent,  $n$ , were determined from these plots. It was found that the deviation from linear relationship in the logarithmic plot was very slight between the values  $\delta = 0.1$  and  $\delta = 0.3$ ; consequently, the data points in this range of strain were used for the determination of  $n$ .

Results are listed in Table II or presented graphically in Figs. 2 through 10. It can be seen readily that all the alloying elements raised the height of the flow curve.

### Tensile Strength and Lower Yield Point

The tensile strength and the lower yield point were increased by addition of each of the alloying elements studied, not considering Al, B, S, Mo, and Ti. The effects of composition on tensile strength and yield point as reported herein are in close agreement with the results of Kramer, Gorsuch, and Newhouse<sup>10</sup> who investigated steels through much broader composition and cooling rate ranges than are represented by the data of this paper, and therefore will not be discussed further.

### Fracture Stress, Fracture Strain, and Energy to Fracture

The fracture stress,  $\sigma_f$ , and the fracture strain,  $\delta_f$ , are represented by the coordinates of the terminal point of the flow curve, and the energy to fracture,  $E_f$ , is the area under this curve to  $\delta = \delta_f$ ; consequently, it is evident that these values are closely related and can best be considered simultaneously.

Fig. 3—Variation of strength and ductility parameters with manganese content.

Since the addition of an alloying element increases the height of the flow curve, it follows that: 1—If the addition of an element increases  $\delta_f$ , it must also increase  $\sigma_f$  and  $E_f$ ; 2—if the addition of an alloying element results in no change in  $\delta_f$ , it must cause an increase in  $\sigma_f$  and  $E_f$ ; 3—if the addition of an alloying element results in a decrease in  $\delta_f$ , it can cause either an increase, or a decrease, or no change in the values of  $\sigma_f$  and  $E_f$ , depending upon the degree of the decrease in  $\delta_f$  and the difference in the heights of the flow curves.

In Table III, the qualitative effects of the alloying elements on  $\delta_f$ ,  $\sigma_f$ , and  $E_f$  are listed; the degree of the influence of the various elements on  $\delta_f$ ,  $\sigma_f$ , and  $E_f$  can be seen in Figs. 2 through 10.

The degree of the accuracy realized in the experimental determination of  $\sigma_f$  is likely rather low, and it is considered that much of the scatter in the composition vs.  $\sigma_f$  curves, as shown in Fig. 2, is due to experimental error. This inaccuracy results from

the difficulty in reading the load of the tension machine at the instant of fracture of the test bars.

It is considered that the melting and heat-treating practices used eliminated, to the maximum possible extent, variations in such metallurgical factors as inclusions and grain size. The maintenance of uniformity of such factors, which can have an appreciable effect on  $\delta_f$ , is especially important since a change in  $\delta_f$  will result in changes in  $\sigma_f$  and  $E_f$ , and composition effects on  $\delta_f$ ,  $\sigma_f$ , and  $E_f$  could thus be masked. Metallographic checks and the uniformity in properties of the base analysis heats indicated the steels were sufficiently uniform to obviate the possibility that such extraneous factors had appreciable effects.

### Rate of Strain Hardening

The rate of strain hardening,  $\Delta\sigma/\Delta\delta$ , or the slope of the nearly straight portion of the flow curve, was found to increase as the height of the flow curve increased. This relationship is illustrated by Fig. 11, in which the slope is plotted against the intercept at zero strain,  $\sigma_i$ .

Lacy and Gensamer in their studies of alloy ferrites<sup>1</sup> found a linear relationship between slope and  $\sigma_i$ , which would require that the ratio of the slope to the stress at  $\sigma_i$  be a constant. An inspection of the last column of Table II indicates that such a simple relationship does not obtain in the steels used in the investigation. Hollomon,<sup>2</sup> moreover, found that for steels the slope increases with increasing strength differently for different carbon contents.

In Fig. 11, the best lines are drawn for the carbon, the silicon, and the copper series. For comparison, curves of Lacy and Gensamer<sup>1</sup> and of Hollomon<sup>2</sup> representing data on binary ferrites and quenched and tempered carbon steels, respectively, are added to the figure.

Subject to the accuracy of the determination of slope, Fig. 11 indicates that the rate of strain hardening at a given strength level varies with composition. For example, if a given increment of strength is achieved by the addition of Si to the base analysis steel, the rate of strain hardening is increased more than if this same strength increment is realized by adding Cu. A best line drawn through the Mn, P, Cr, or Ni would not be greatly displaced from the Cu or C line; a V line would be about parallel and slightly below the Cu line. It is interesting to note that the binary ferrite data of Lacy and Gensamer fall almost on the carbon line at low carbon levels, and that Hollomon's quenched and tempered 0.20 pct C series indicates that such materials have a much lower rate of strain hardening than pearlitic steels.

### Strain Hardening Exponent

In Fig. 12, the strain hardening exponent,  $n$ , is plotted against intercept at zero strain,  $\sigma_i$ . A

Table IV. Standard Deviations Based on Duplicate Tests of 20 Base Analysis Heats

| Parameter                            | (Standard Deviation)      |
|--------------------------------------|---------------------------|
| Tensile strength                     | 2160 psi                  |
| Yield point                          | 2050 psi                  |
| Fracture stress, $\sigma_f$          | 6680 psi                  |
| Stress at 0.2 strain, $\sigma_{0.2}$ | 2500 psi                  |
| Fracture strain, $\delta_f$          | 0.049                     |
| Strain hardening exponent, $n$       | 0.0113                    |
| Slope, $\Delta\sigma/\Delta\delta$   | 4,214 psi per in. per in. |
| Energy to fracture, $E_f$            | 5,310 in. lb per cu in.   |
| Percent reduction of area            | 1.65 pct                  |
| Percent elongation in 1.4 in.        | 2.82 pct                  |

straight line is drawn through the approximate center of the scatter zone of these data. It is considered that most of the scatter in these data represents experimental error rather than differences in the effects of alloying elements on  $n$ . This error results largely from the necessity of considering only those data within a relatively narrow range of strain values, over which there is very little deviation from the power law, for the establishment of the slope of the  $\ln\sigma$ - $\ln\delta$  plot. For example, if data between  $\delta = 0.15$  and  $\delta = 0.25$  are used for the determination of  $n$  at a strength level which gives a value of  $\sigma_{0.2}$  of approximately 80,000 psi, and if an accuracy of  $\pm 1/2$  pct is assumed in the weighing system of the testing machine, the variation in the determination of  $n$  will be  $\pm 0.01$  due alone to errors in load reading. This error can account for about half of the scatter of the data of Fig. 12. Another possibility of serious error results from the fact that in the range of strain over which  $n$  is determined, the neck is in the initial stages of formation; consequently, the process of locating the minimum diameter of the test bar is difficult and error in the measurement of strain can result. It is interesting, also, to note that the degree of the scatter in the value of  $n$  reported in this paper is approximately of the same order as the scatter reported by Gensamer<sup>4</sup> for steels of various compositions and heat treatments. In view of these possibilities of experimental error in the value of  $n$ , it must be concluded that if there are any effects of the alloying elements studied on the value of  $n$  they are too small to be detected with the present experimental technique.

### Scatter on the True-Stress, True-Strain Test Results

As noted above, a considerable amount of experimental error is to be expected. The reliability of the data and the reality of the trends showing the effects of alloying elements on properties are subject to this error, particularly in those instances in which the total change in the property throughout the series is small. An approximation of the limiting amount of experimental error therefore is considered to be desirable.

The lack of a sufficient number of data from one steel prevented a statistical study of the scatter in one heat. However, it was possible to estimate an upper limit of the scatter by determining the standard deviation in the properties of 20 different heats (the 20 heats were tested in duplicate, thus providing 40 tests) of approximately 0.30 pct C, 1.00 pct Mn, 0.30 pct Si, at least one of which occurred in each series. The maximum variation in composition of these base analysis heats were 0.03 pct C, 0.05 pct Mn, and 0.03 pct Si. These values of standard deviations in properties of the 20 base analysis heats are listed in Table IV.

If it is assumed that the variation in physical

Table III. Effects of Elements on  $\sigma_f$ ,  $\delta_f$ , and  $E_f$

| Alloying Element | Fracture Strain, $\delta_f$ | Fracture Stress, $\sigma_f$ | Energy to Fracture, $E_f$ |
|------------------|-----------------------------|-----------------------------|---------------------------|
| Carbon           | Decreases                   | Constant                    | Decreases                 |
| Manganese        | Increases slightly          | Increases                   | Increases                 |
| Silicon          | Decreases                   | Increases                   | Decreases                 |
| Phosphorus       | Decreases                   | Constant                    | Decreases                 |
| Copper           | Decreases                   | Increases                   | Decreases slightly        |
| Chromium         | Constant                    | Increases                   | Increases                 |
| Nickel           | Constant                    | Increases                   | Increases                 |
| Vanadium         | Decreases                   | Increases                   | Decreases                 |

Fig. 11—Variation of the intercept ( $\sigma_i$ ) with rate of strain hardening ( $\Delta\sigma/\Delta\delta$ ).

The vertical line represents the value of four times the standard deviation of slope in 40 tests of 20 different base analysis heats.

Fig. 12—Variation of intercept ( $\sigma_i$ ) with strain hardening exponent ( $n$ ).

The vertical line represents the value of four times the standard deviation of  $n$  in 40 tests of 20 different base analysis heats.

properties is Gaussian, then the range of plus or minus twice the standard deviation will include 95 pct of the test results. For ready comparison, the value of plus or minus twice the standard deviation ( $\pm 2\sigma$ ) of slope is indicated in Fig. 11, of the strain hardening exponent in Fig. 12, and of  $\sigma_f$ ,  $\delta_f$ ,  $\sigma_{0.2}$ ,  $E_f$ , T.S., and Y.P. in Fig. 2.

In order to demonstrate that the addition of an element changes a given physical property, it would be necessary that the value of the property of the steel without the addition differ from its value with the addition by at least 2.8 times the standard deviation. An inspection of Figs. 2 to 10 will show that this condition is not met in all cases, for ex-

ample, in the Mo series. However, the near-certainty that the standard deviations in properties of the 20 different heats of similar composition would be greater than the standard deviation in single split heats lends credence to the trends in the properties of those series of split heats whose properties changed by less than the 2.8 times the standard deviations shown.

### Summary

1—The effects of C, Mn, Si, P, Cu, Cr, Ni, Mo, V, Al, B, S, and Ti on the true-stress, true-strain curves of pearlitic steels were investigated.

2—All the elements studied except Al, B, S, Mo, and Ti were found to increase the height of the flow curve; effects of Al, B, S, Mo, and Ti were too small to permit reliable evaluation.

3—The rate of strain hardening was found to increase as the height of the flow curve increased; the degree of this increase varied with composition.

4—The strain hardening exponent was found to decrease as the height of the flow curve increased; however, the effects of composition on this relationship, if such effects exist, were too small to be detected by the experimental methods employed.

5—The ratio of the rate of strain hardening to the intercept at zero strain was found to be variable; in this respect the pearlitic steels of this investigation differed from binary ferrites.

6—The energy to fracture was increased by Mn, Ni, and Cr and was decreased by C, Si, P, Mo, Cu, and V.

### Acknowledgment

The authors gratefully acknowledge the encouragement and interest of O. T. Marzke, Superintendent of the Metallurgy Division, and the able assistance of W. S. Kenton and G. G. Gregg, who conducted the tests.

# Thermodynamics of Iron-Silicate Slags: Slags Saturated with Gamma Iron

by R. Schuhmann, Jr. and P. J. Ensio

**As a first step in a study of the physical chemistry of copper-smelting slags, experimental measurements were made of the oxygen pressure of simple iron-silicate slags in equilibrium with solid iron. The experiments consisted in bubbling  $\text{CO}_2$ -CO mixtures through the slags in iron crucibles and in finding the equilibrium ratios of  $\text{CO}_2$  to CO. From the data, activities and partial molal heats of solution FeO and  $\text{SiO}_2$  in the slags were calculated.**

THE ternary system  $\text{FeO-Fe}_2\text{O}_3\text{-SiO}_2$  is the simplest system which can represent adequately the important chemical properties of the slags formed in matte smelting and converting. Accordingly, the experimental study of slags in this system was started as the first step in a general research program on the thermodynamics of copper smelting. A recent paper by one of the authors<sup>1</sup> outlines this general research program and shows in some detail how information on thermodynamic properties of iron-silicate slags, especially information on oxygen activities, is essential to a full understanding of the chemistry of copper smelting. The  $\text{FeO-Fe}_2\text{O}_3\text{-SiO}_2$  system also is the basis of slags produced in other processes, such as acid steelmaking processes, and is important in relation to the behavior of silicious refractories. In addition, data on the physicochemical properties of iron-silicate slags should contribute to a general understanding of the nature of slags, since at present such data for all kinds of slags are relatively meager.

The principal quantitative information already available on iron-silicate slags consists in Bowen and Schairer's constitution diagram for slags in equilibrium with metallic iron,<sup>2</sup> Darken and Gurry's complete and precise thermodynamic study of the

Fe-O system,<sup>3,4</sup> and Darken's study of the phase equilibria in the Fe-Si-O system.<sup>5</sup> From the results of this previous work, it was clear that a complete thermodynamic study of ternary iron-silicate melts was a major undertaking which would have to be broken down into parts, including the working out of the ternary equilibrium diagram as well as extensive activity measurements on slags.

The experimental measurement of oxygen activity, using  $\text{CO-CO}_2$  and other gas mixtures as yardsticks of oxygen activity, was the basis of Darken and Gurry's study of the Fe-O system. From the experimental measurements of oxygen activities over a large range of temperatures and compositions, they were able to calculate the activities of other species such as Fe, FeO,  $\text{Fe}_3\text{O}_4$ , etc., and also the other important thermodynamic properties in the Fe-O system. At the start of the present investigation, it appeared that the same approach would be fruitful for the study of iron-silicate melts. Also, the experimental measurement of oxygen activities seemed particularly attractive because oxygen activity itself is a quantitative measure of oxidizing or reducing power, which is an important variable in copper-smelting slags. The slag compositions in equilibrium with  $\gamma$ -Fe appeared most suitable for the first investigation of this kind, for the following reasons: 1—Good constitution data<sup>2</sup> were available. 2—An iron crucible could be used, thus affording a simple solution to the refractory problem without introducing contamination. 3—With Fe activity fixed, at unity with respect to a standard state of solid Fe, measurements of O activity could be followed by simple calculations of activities of FeO and other Fe-O complexes and of  $\text{SiO}_2$ . 4—This starting point afforded several possibilities for cross-checking with previous work,

R. SCHUHMAN, JR., Member AIME, is Associate Professor, Department of Metallurgy, Massachusetts Institute of Technology, Cambridge. P. J. ENSIO, Ville St. Laurent, Quebec, was formerly Graduate Student, Massachusetts Institute of Technology.

Discussion of the paper, TP 3031D, may be sent (2 copies) to AIME by July 1, 1951. Manuscript, Oct. 16, 1950. St. Louis Meeting, February 1951.

This paper is based on a thesis by Mr. Ensio submitted in partial fulfillment of requirements for the degree of Doctor of Science at Massachusetts Institute of Technology.

especially with the work of Darken and Gurry and the work of Bowen and Schairer.

Summarizing, the experimental work reported herein consisted in the determination of  $\text{CO}_2:\text{CO}$  ratios in gas mixtures at equilibrium in the system:

gas:liquid slag: $\gamma$ -iron

Determinations were made over the whole range of slag compositions from wüstite saturation to silica saturation, and at temperatures from  $1250^\circ$  to  $1350^\circ\text{C}$ . Slags were analyzed chemically for  $\text{FeO}$ ,  $\text{Fe}_2\text{O}_3$ , and  $\text{SiO}_2$ . The composition range covered was 61 to 93 pct  $\text{FeO}$ , 0.5 to 8.5 pct  $\text{Fe}_2\text{O}_3$ , and 0 to 39 pct  $\text{SiO}_2$ . Equilibrium  $\text{CO}_2:\text{CO}$  ratios were determined also at various temperatures for the two univariant systems:

gas:liquid slag: $\gamma$ -iron:wüstite

gas:liquid slag: $\gamma$ -iron:tridymite

From the experimental data relating equilibrium  $\text{CO}_2:\text{CO}$  ratios to slag composition, thermodynamic calculations were made of the activities of  $\text{FeO}$  and  $\text{SiO}_2$  and of the partial molal heats of solution of  $\text{FeO}$  and  $\text{SiO}_2$  in the slags.

### Experimental Methods

The experimental procedure was as follows: A mixture of stock iron-silicate slag with iron oxide or silica was melted in an iron crucible under a  $\text{CO}_2\text{-CO}$  atmosphere and brought to the desired temperature. Then a mixture of  $\text{CO}_2$  and  $\text{CO}$  was bubbled through the melt, and analyses were made of the ingoing gas mixture and of the mixture after bubbling through the melt. The gas composition was adjusted until the analyses of entering and leaving gases became and remained the same, and the  $\text{CO}_2:\text{CO}$  ratio thus finally obtained was considered an equilibrium value. After equilibrium was reached in this way, the melt was sampled and the samples were analyzed for  $\text{FeO}$ ,  $\text{Fe}_2\text{O}_3$ , and  $\text{SiO}_2$ .

**Furnace and Crucible Assembly:** Fig. 1 shows the complete furnace and crucible assembly. The furnace was a platinum-resistance furnace of essentially standard design built around a vertical aluminum tube of 3-in. bore and 18-in. length. Furnace temperature was controlled automatically by an electronic controller developed by Gordon and Tainton.<sup>9</sup> In this control circuit, the platinum furnace winding is made to be one arm of an ac bridge, and the current through the winding is controlled to maintain the resistance of the platinum winding constant. This arrangement performed well, though requiring occasional expert attention, and maintained constant crucible temperatures within  $\pm 0.5^\circ\text{C}$  for several hours and within  $\pm 2^\circ\text{C}$  for periods of several days.

The crucible assembly was held in a vertical porcelain tube (McDaniel),  $30 \times 2\frac{3}{4}$  in. outside, mounted to extend about 8 in. below and 4 in. above the furnace core. The porcelain tube had water-cooled, brass heads clamped and sealed to

the tube with rubber gaskets. The upper brass head supported the crucible assembly and was provided with tubes for access to the crucible. The lower brass head carried a tube for admitting gas and an opening through which a thermocouple protection tube was inserted and sealed. Arrangements were made so that either a  $N_2$  or a  $CO_2$ - $CO$  atmosphere could be maintained in the porcelain tube around the crucible, independently of the atmosphere within the crucible.

The crucible assembly is shown more clearly in Fig. 2. The iron crucible, 1½-in. diam and 3¾-in. deep inside, was turned from a cylinder of Armco iron and was provided with a thermocouple well in the bottom. The iron cover was welded to the crucible and the crucible was supported by the two low-carbon steel tubes, ½-in. ID, welded to the cover and extending up into the brass head. Inside one of these tubes was the bubbler tube, made of steel tubing with a 2-in. long replaceable tip made from Armco iron. The bubbler tube could be moved up or down through a gas-tight seal in the head, so that it could be raised out of the slag if desired. The main path of gas flow through the crucible assembly was in the bubbler tube, through the slag and crucible, and then out in the annular space between the bubbler tube and the larger steel tube around the bubbler tube. The other ½-in. steel tube provided access to the crucible for sampling, adding materials, observation, etc. Normally it was closed with a sight glass clamped and rubber sealed to the top opening of the access tube, as shown in Fig. 1. The whole crucible assembly was made as compact and gas tight as possible, so that the gas composition inside could be controlled independently of that in the surrounding furnace tube. In this way a system was obtained for which the outlet gas composition would respond quickly and fully to changes in the reacting phases. Such response, of course, greatly facilitated the location of equilibrium by the method of comparing ingoing and outgoing gas analyses.

The average charge for an equilibrium run was around 150 g of slag, which in the molten state filled the crucible to a depth of under 50 mm. The gas mixture was passed through the slag at the rate of about 100 ml per min.

**Temperature Measurement:** Temperatures were measured with Pt—Pt-Rh thermocouples calibrated at the melting point of gold. The thermocouple, in a porcelain protection tube, was inserted up through the bottom of the furnace tube into the well on the crucible bottom and left in position during each run.

Before the equilibrium runs were made, the temperature distribution in the empty crucible was investigated in some detail. Readings of couples inserted in porcelain protection tubes through the access tube to various levels in the crucible were compared to readings obtained simultaneously with another couple in the well on the crucible bottom. Inside the crucible from the bottom upwards the temperature decreased about 0.2°C in the first 25 mm and then decreased further about 3°C in the next 25 mm, so that the slag was in a zone in which the temperature was probably uniform within about 3°C. The temperature dropped more sharply in the upper part of the crucible, readings with the junction just at the crucible lid falling about 20°C below those near the bottom. The couple inserted from below into the well gave readings from 10° to 16°C below those obtained inside the crucible

near the bottom, and the temperature gradient in the well appeared to be steeper than in the crucible. In view of these characteristics, the thermocouple in the well, with which all final temperature measurements were made, was calibrated against a couple inside the crucible with the furnace at temperature but before adding slag for each run. The correction thus measured was applied to all read-

Fig. 3—Log  $p_{CO_2}/p_{CO}$  vs.  $10^4/T$  for equilibria with Fe-saturated slags of varying  $SiO_2$  content.

ings made during the run. This correction was checked several times by comparing the corrected temperature with the reading of a couple in a porcelain or silica protection tube, with a thin iron sheath on the lower end to prevent attack by the slag, actually immersed in the slag. Difficulties in maintaining protection tubes inside the crucible prevented the more extensive use of immersed couples.

On the basis of the temperature-distribution measurements outlined above, the temperatures reported in the experimental data are thought to represent actual slag temperatures to  $\pm 3^\circ C$ .

**Preparation of  $CO_2$ -CO Mixtures:** The gas mixtures, consisting of purified  $CO_2$  and CO at a total pressure of substantially 1 atm, were prepared by essentially the same procedure as that described by Darken and Gurry<sup>9</sup> using flowmeters with pressure bleeders up and downstream to maintain automatically a constant gas composition. No difficulty was experienced in holding the gas composition constant to well within 0.1 pct  $CO_2$  for long periods.

The gas trains were of all-glass construction, except for short rubber connections at the main furnace, the  $CO_2$  tank, and the furnace in which  $CO_2$  was reduced to CO with graphite.

**Gas Analyses:** Two methods of analyzing the incoming and outgoing gas mixtures were used. During the period of adjustment of the gas composition, the outgoing gas was continuously analyzed and the analysis was recorded by means of a Leeds and Northrup thermal-conductivity unit and Micro-max recorder. This automatic and quick gas analysis saved a large amount of time and analytical labor and is strongly recommended for studies in which comparison of ingoing and outgoing gas analyses is used as a criterion of equilibrium. After the thermal-conductivity analysis indicated the in-

going and outgoing gas compositions to be the same to  $\pm 0.2$  pct  $CO_2$ , final adjustments and determinations of equilibrium  $CO_2$ :CO ratios were made with chemical analyses of the gases.

The chemical procedure of gas analysis was as follows: First the  $CO_2$  was absorbed in a train of ascarite and anhydron, then the CO was oxidized to  $CO_2$  in a copper-oxide combustion furnace, and finally the  $CO_2$  formed from CO was absorbed in a second train of ascarite and anhydron. Purified nitrogen was used for flushing the whole analytical train before and at the end of each analysis. By this procedure, both  $CO_2$  and CO were measured as weights of  $CO_2$ , and the weight ratio was considered to be the ratio of partial pressures, assuming ideal gas behavior. For the gas mixtures from 10 to 25 pct  $CO_2$  (balance CO) used in this investigation, the analyses were readily reproducible to  $\pm 0.05$  pct  $CO_2$ .

**Sampling and Analyses of Slags:** After equilibrium was established, the slag was sampled by inserting a long,  $1/4$ -in. diam, Armco-iron rod into the molten slag for a few seconds. The hot sample of 1 to 4 g then was lifted up into the cold part of the furnace and allowed to cool in contact with the  $CO_2$ -CO furnace atmosphere. Normally three to five duplicate samples were taken from each equilibrium slag and stored immediately in closed glass bottles.

Three determinations, namely silica, total iron, and ferric iron, were made to determine the slag composition. The first two determinations were straight-forward and could be carried out by standard methods to an accuracy of 0.1 pct. However, some difficulties were experienced in obtaining reliable and reproducible analyses for ferric iron. The method finally adopted consisted in dissolving a slag sample in HCl under a  $CO_2$  atmosphere and then titrating with  $TiCl_3$ , using  $NH_4SCN$  as indicator and maintaining the  $CO_2$  atmosphere at all steps. Part of the difficulty in obtaining reproducible results was traced to oxidation of the samples during grinding in the agate mortar, so that finally the samples were ground quickly only to -20-mesh. A longer time was required for bringing these coarse samples into solution.

The results of the slag analyses, calculated to pct FeO, pct  $Fe_2O_3$ , and pct  $SiO_2$ , added up to between 99.25 and 100.0 total pct in all cases and to between 99.6 and 100.0 pct in the majority of samples. Accordingly, the percentages of FeO,  $Fe_2O_3$ , and  $SiO_2$  were corrected slightly to add up to 100 pct exactly, and are so reported in the experimental data.

**Materials:** The stock fayalite slag was prepared in a large Armco-iron crucible from Baker cp ferric oxide, Mallinckrodt hydrogen-reduced iron powder,

and precipitated silica. A mixture calculated to yield a slag corresponding to fayalite ( $2\text{FeO} \cdot \text{SiO}_2$ ) in composition was heated at  $1350^\circ$  to  $1400^\circ\text{C}$  for complete fusion. The temperature was then lowered to  $1300^\circ\text{C}$  and the molten slag was kept at that temperature for 1 hr to let it become homogeneous and approach equilibrium with the iron crucible. The slag was then cast into an iron mold, cooled, crushed, and screened. The fraction  $-6 + 20$ -mesh was used for the stock. Chemical analysis gave 67.3 pct FeO, 4.1 pct  $\text{Fe}_2\text{O}_3$  and 28.4 pct  $\text{SiO}_2$ .

The iron oxide was prepared by oxidizing a bar of Armco iron in an electric furnace at  $1200^\circ\text{C}$ , collecting the scale, and screening. The fraction  $-6 + 20$ -mesh was again used for making up the slags and was found to analyze 71.2 pct FeO, 28.5 pct  $\text{Fe}_2\text{O}_3$ .

The silica was prepared from silica glass (99.8 pct  $\text{SiO}_2$ ) by crushing and then screening out the desired  $-6 + 20$ -mesh fraction.

### Chemical Reactions and Establishment of Equilibrium

The principal reactions for which equilibrium must be established are those between the gas and the slag and between the iron crucible and the slag, which can be written:

Reaction 1 was found to be quite rapid when a gas mixture was bubbled through liquid slags under the conditions of the present work. In fact for low-silica slags, the gas leaving the melt generally had a  $\text{CO}_2:\text{CO}$  ratio close to that corresponding to equilibrium with the slag, regardless of the  $\text{CO}_2:\text{CO}$  ratio in the gas brought in through the bubbler tube. For high-silica slags the reaction was slower, but still rapid enough that there was no difficulty in detecting the direction of reaction by comparison of ingoing and outgoing gas analyses. In addition to the high reaction rates afforded by the intimate gas-liquid contact, the bubbling method furnished good agitation of the slag and also eliminated the possibility of errors due to thermal diffusion. Accordingly, the very satisfactory experience in the present work with the procedure of bubbling the gas through the melt has led to the adoption of the

same technique in other high-temperature, gas-liquid equilibrium studies in this laboratory.

Bowen and Schairer found that equilibrium in reaction 2 was quickly reached between iron crucibles and iron silicate slags. Slow attainment of equilibrium in this reaction in the present work would have caused a drift in the measured  $\text{CO}_2:\text{CO}$  equilibrium ratios, and such a drift never was found. Moreover, by the time the final equilibrium was established for each slag, the slag had been at constant temperature and at substantially constant composition in the iron crucible for several hours.

Theoretically, there are two possible procedures for finding the equilibrium gas and slag compositions: 1—Bring a given slag mixture to equilibrium with solid iron and then vary the gas composition until the equilibrium  $\text{CO}_2:\text{CO}$  ratio is found. 2—Fix the gas composition, the  $\text{CO}_2:\text{CO}$  ratio, and allow reactions 1 and 2 to occur until the slag reaches a composition in equilibrium with the gas. Simple stoichiometric calculations show that the second procedure would be very time-consuming, so the first procedure was used throughout the work. The stoichiometric calculations also showed the impracticality of using rate of change of slag analysis as a criterion of equilibrium.

**Secondary Reactions:** Other reactions which could be expected in the gas-slag-metal system are the following:

Reactions 3, 4, and 5 undoubtedly occurred, but quantity estimates based on known equilibrium data for these reactions indicated their effects on the experimental results would be negligible. On the

Fig. 5—Log  $p_{CO_2}/p_{CO}$  vs.  $10^4/T$  for equilibria with slag:wüstite: $\gamma$ -iron.

Results of present work are given by black circles; the straight line and the points of invariant equilibria NJ are based on work of Darken and Gurry.

other hand, it appeared that the effects of reactions 6 and 7 could not be ignored. That is, approximately equal reaction rates to the right in reaction 1 and in either reaction 6 or 7 would result in no net change in gas composition through the system, thus giving a false indication of equilibrium in reaction 1.

Reaction 6 has been studied recently by Smith.<sup>7</sup> Smith's work showed that at temperatures of 1150° to 1350°C, the gas mixtures used in the present investigation, namely 10 to 25 pct  $CO_2$ , balance  $CO$ , would be decarburizing to Armco iron; that is, reaction 6 would tend to go to the left and only a small total amount of C could be involved in reaching equilibrium, starting with a new crucible. However, at lower temperatures in the steel tubes through which the gas enters and leaves the crucible a zone of conditions most favorable to carburization of the iron is to be expected. Similarly, equilibrium data for reaction 7 show no possibility of graphite formation in the crucible and high-temperature zone of the system. However, when both equilibrium and reaction rate information on this reaction are considered, again a zone at intermediate temperature most favorable to C deposition is to be expected in the steel tubes above the crucible. Such a zone was readily observed, especially with gases of 90 pct or more  $CO$ .

The effects of the side reactions of carburization and C deposition were studied by making a blank run at 1250°C on a new, empty crucible assembly. Data for this run, given in Table I, indicate that these reactions had little effect on gas composition for gases containing 12 pct or more  $CO_2$  but had a serious effect for gases lower in  $CO_2$ .

To minimize the effects of the side reactions, the following procedure was adopted for the gas-slag equilibrium runs. When it appeared that the gas composition was adjusted substantially to equilibrium with the slag, the bubbler tube was raised out of the melt so that the gas merely passed over the melt and then out to the analytical train. Raising the bubbler tube should reduce the rate of the gas-slag reaction without affecting the rates of the side reactions. Accordingly, when gas-slag equilibrium is reached, the analysis of the outgoing gas should be the same with the bubbler up or down, although the outgoing gas might be higher in  $CO_2$  than the incoming gas because of the side reactions. Most of the runs were continued until the  $CO_2$  percentages in the incoming gas, the outgoing gas with

bubbling, and the outgoing gas without bubbling agreed within 0.2 pct, but in a few cases such close agreement was not reached even after rather long runs.

## Experimental Results

In all, 33 equilibrium runs were made, the duration of the runs from start of bubbling at temperature to the end averaging about 7 hr each. Of these 33 runs, 23 were on slags of varying silica content at temperatures ranging from 1250° to 1400°C, seven were on wüstite-saturated slags at temperatures from 1250° to 1350°C, and three were on silica-saturated slags at temperatures from 1250° to 1350°C.

Table II gives the data on gas-slag-iron equilibrium for slags of varying silica content. In Fig. 3 is given a plot of  $\log p_{CO_2}/p_{CO}$  against  $10^4/T$  from the same data. For slags of given  $SiO_2$  content, it can be seen that the points are fitted by straight lines within the experimental error. All the lines in Fig. 3 are drawn with a slope of 0.264, even though slightly different slopes would result if each line were drawn independently with best fit to the three experimental points. The reasons for presenting the data in this way are discussed later. However, it should be pointed out that the largest deviations from the lines, obtained with the data for 27.1 pct  $SiO_2$ , correspond to an error of only 0.3 pct  $CO_2$  in the gas analysis or only 10°C in the temperature.

Fig. 4 shows the variation of equilibrium pct  $Fe_2O_3$  with pct  $SiO_2$  for the slags in iron crucibles at various temperatures. Also shown are the previous results of Bowen and Shairer at liquidus temperatures and the recommended values of Darken and Gurry for 0 pct  $SiO_2$  slags. The results are not as concordant as might be desired, probably owing to difficulties in making accurate analyses for  $Fe_2O_3$ . However, certain trends are evident. First, the equilibrium pct  $Fe_2O_3$  clearly decreases with increasing pct  $SiO_2$ , and the present results are in semiquantitative agreement on this score with the findings of Bowen and Schairer. Second, for slags of fixed pct  $SiO_2$  in Fe crucibles, the equilibrium pct  $Fe_2O_3$  decreases very slowly with increasing temperature and appears least affected by temperature at high pct  $SiO_2$ . Bowen and Schairer concluded that the effect of temperature on pct  $Fe_2O_3$  in the Fe-saturated silicate melts was too small to be detected by their analytical methods. Similarly, Darken and Gurry's experimental results on Fe-saturated melts at 0 pct  $SiO_2$  were too scattered to furnish a good direct measure of this change, but their recommended constitution diagram for the

\* Average values from duplicate analyses corrected to 100 pct. In Runs 24-26 analyses were on samples taken from the homogeneous melt at about 50°C above the final equilibrium temperature. In Runs 27-30 analyses are on samples of the saturated slag at the equilibrium temperature.

Fe-O system shows a decrease of 2.6 pct Fe<sub>2</sub>O<sub>3</sub> per 100°C increase in temperature.

Table III gives the results obtained in equilibrium measurements on slags saturated both with wüstite and with solid iron. The procedure used in these runs was as follows: The high-FeO slags were melted and held for 2 hr at 1350°C to insure homogeneity and equilibrium with the crucible. Then the system was cooled and brought to thermal equilibrium at a temperature for which, according to Bowen and Schairer's constitution diagram, substantial precipitation of wüstite should occur. The equilibrium CO<sub>2</sub>:CO ratio was determined by the usual procedure. Then, stock slag was added to the crucible to increase the SiO<sub>2</sub> content by 2 or 3 pct and the equilibrium CO<sub>2</sub>:CO ratio again determined. A check of the two CO<sub>2</sub>:CO ratios for different SiO<sub>2</sub> percentages in the mixture was taken as evidence of wüstite saturation.

A plot of log CO<sub>2</sub>/CO against 10<sup>4</sup>/T for the gas-slag-iron-wüstite equilibria is given in Fig. 5. The straight line is represented by the equation:

$$\log \frac{p_{CO_2}}{p_{CO}} = \frac{850}{T} - 1.068 \quad [8]$$

and is based on the data for the gas-iron-wüstite equilibria recommended by Darken and Gurry<sup>3</sup> on the basis of their own experimental work as well as the earlier work of Chipman and Marshall,<sup>8</sup> Emmett and Schultz,<sup>9,10</sup> and Schenck and coworkers.<sup>11</sup> The lower temperature terminus of the line (Darken's<sup>5</sup> invariant point 4) is at the temperature at which the slag is in equilibrium with γ-Fe, wüstite, and fayalite; the higher temperature terminus (point NJ) is at the melting point of wüstite. The results of the present work, with slag as an additional phase and silica as an additional component, clearly confirm the results of the previous work. The maximum deviation of the new data from the relation recommended by Darken and Gurry corresponds to a difference of only 0.4 pct CO<sub>2</sub> in the analysis of the CO-CO<sub>2</sub> mixture.

Table IV gives the results obtained on slags saturated with silica and with solid iron. For these runs a slag mixture estimated to be just under saturation with SiO<sub>2</sub> was charged into the iron crucible and fused at 1400°C. A rod of silica glass was inserted into the melt and left for several hours, with occasional removal for inspection. The rod was attacked strongly at the start, but after 6 hr no further attack was noticeable. A sample of the slag at this stage analyzed 39.7 pct SiO<sub>2</sub>, in good agreement with expectations from Bowen and Schairer's

\*\* Darken's value for the CO<sub>2</sub>:CO ratio at the quintuple point in which iron, silica, fayalite, and slag are all present at equilibrium. Bowen and Schairer's values for temperature and composition.

Fig. 6—Log p<sub>CO2</sub>/p<sub>CO</sub> vs. 10<sup>4</sup>/T for equilibria with slag:silica:γ-iron. Results of present work are given by black circles; invariant point 5 is taken from Darken.

data. After it appeared that silica saturation at 1400°C had been attained in this way, the temperature was successively lowered for the determinations of equilibrium CO<sub>2</sub>:CO ratios at 1352°, 1310°, and 1260°C. Table IV also includes data taken from previous work for the invariant point at which slag, iron, silica, and fayalite are in equilibrium.

Fig. 6 shows the relation between log p<sub>CO2</sub>/p<sub>CO</sub> and 10<sup>4</sup>/T for the SiO<sub>2</sub>-saturated slags. The straight line was drawn from the invariant point 5, giving most weight to the experimental point at lowest temperature, and follows the equation:

$$\log \frac{p_{CO_2}}{p_{CO}} = \frac{2940}{T} - 2.747 \quad [9]$$

A diagram summarizing the now available information on the relation of log p<sub>CO2</sub>/p<sub>CO</sub> to 10<sup>4</sup>/T for the entire range of stability of iron-silicate slags in contact with solid iron is given in Fig. 7. This range of stability is shown by the closed area C-NJ-4-5-D, and the boundary lines and curves correspond to the following limiting conditions:

- Line NJ-4: Wüstite saturation
- Curve 4-5: Fayalite saturation
- Line 5-D: Silica saturation
- Line D-C: Melting point of iron
- Line C-NJ: Slags of 0 pct SiO<sub>2</sub>

These boundaries were located as follows:

NJ-4: Line recommended by Darken and Gurry<sup>3</sup> from melting point of wüstite to point 4 at the fayalite eutectic temperature which was found by Bowen and Schairer.<sup>2</sup>

4-5: Curve from point 4 on line NJ-4 to point 5 recommended by Darken,<sup>5</sup> based on data by Schenck, Franz, and Laymann,<sup>12</sup> Bowen and Schairer,<sup>2</sup> and Darken and Gurry. Points a, b, c, and d located by extrapolation of present experimental data to fayalite-saturation temperatures which were read from Bowen and Schairer's constitution diagram.

5-D: Straight line from point 5 through experimental points of present investigation.

C-NJ: Straight line recommended by Darken and Gurry,<sup>4</sup> to point C at the melting point of oxygen-saturated iron as determined by Chipman and Marshall.

Letting  $k$  represent the equilibrium constant:

$$a_{\text{FeO}} = \frac{1}{k} \frac{p_{\text{CO}_2}}{p_{\text{CO}}} \quad [11]$$

for the slags in equilibrium with  $\gamma$ -Fe ( $a_{\text{Fe}} = 1$ ). Choice of an appropriate standard state for FeO is a little troublesome. In the first place, a pure FeO phase does not exist. Second, in the whole range of iron-saturated melts studied there is no solution whose composition does not change with temperature. That is, the experimental data are for compositions and temperatures on the iron-saturation surface in the ternary constitution diagram, and this surface is not a vertical section. However, the composition variation with temperature is small enough so that no serious difficulties are introduced by taking the standard state of FeO as the  $\gamma$ -Fe-saturated, 0 pct SiO<sub>2</sub> slag; that is, the pure Fe-O melt in equilibrium with  $\gamma$ -Fe. Adopting this standard state, the equilibrium constant  $k$  for reaction 10 can be evaluated from Darken and Gurry's recommended equilibrium values of  $p_{\text{CO}_2}/p_{\text{CO}}$  for the system of liquid iron oxide and  $\delta$ -Fe, see Table VIII, ref. 4, applying the small correction for the change from  $\delta$ -Fe to  $\gamma$ -Fe. These calculations give:

$$\log_{10} k = \frac{2640}{T} - 2.157 \quad [12]$$

Combining this relation with eq 11 gives:

$$\log a_{\text{FeO}} = \log \frac{p_{\text{CO}_2}}{p_{\text{CO}}} - \frac{2640}{T} + 2.157 \quad [13]$$

This equation can now be used to calculate  $a_{\text{FeO}}$  for all the experimentally determined equilibria. Results of these calculations for the 33 equilibrium runs are given in Table V. Table V also includes calculated mol fractions taking Fe, O, and SiO<sub>2</sub> as the three slag components ( $N_{\text{Fe}} + N_{\text{O}} + N_{\text{SiO}_2} = 1$ ).

The outstanding and in fact entirely unexpected feature of the set of values of  $a_{\text{FeO}}$  for slags of different SiO<sub>2</sub> contents is that for a given pct SiO<sub>2</sub>,  $a_{\text{FeO}}$  does not vary with temperature. For five out of the seven slags for which  $a_{\text{FeO}}$  was measured at different temperatures,  $a_{\text{FeO}}$  is constant to within about 1 pct as the temperature varies. For the 17.2 pct SiO<sub>2</sub> slag,  $a_{\text{FeO}}$  increases only about 2 pct from 1264° to 1364°C. The largest variation, for the 27.1 pct SiO<sub>2</sub> slag, is an increase of about 5 pct in  $a_{\text{FeO}}$  over a range of 100°, and in the absence of a definite trend for the other slag compositions it appears that this variation might be a result of experimental error. From eq 13 used in calculating  $a_{\text{FeO}}$  from the data, constant  $a_{\text{FeO}}$  means that a plot of  $\log p_{\text{CO}_2}/p_{\text{CO}}$  against  $10^4/T$  will have a slope of 0.2640. Accordingly, the representation of the data in Fig. 3 and Fig. 7 by straight lines of slope 0.2640, to which attention was called previously, reflects the conclusion that for a given slag  $a_{\text{FeO}}$  does not vary with temperature, within experimental error.

The relation of  $a_{\text{FeO}}$  to temperature for slags saturated with  $\gamma$ -iron and wüstite can be expressed by combining eqs 8 and 13 to obtain:

$$\log a_{\text{FeO}} = -\frac{1790}{T} + 1.089 \quad [14]$$

As can be seen in Table Vb, the experimental figures for  $a_{\text{FeO}}$  fit this equation based on Darken and Gurry's work to within about 2 pct.

D-C: Straight line from point C, with slope corrected slightly from the vertical to allow for effect of oxygen on the melting point of iron. Point D found by intersection of lines from C and from 5. This location of D at 1530°C,  $\log p_{\text{CO}_2}/p_{\text{CO}} = -1.118$  ( $p_{\text{CO}_2}/p_{\text{CO}} = 0.076$ ) is to be compared with the estimate given by Darken<sup>5</sup> of 1525°C,  $\log p_{\text{CO}_2}/p_{\text{CO}} = -1.16$  ( $p_{\text{CO}_2}/p_{\text{CO}} = 0.069$ ).

Attention should be called to the fact that the lines drawn for the slags of varying SiO<sub>2</sub> content all have slopes of 0.264 and thus are substantially parallel to line NJ-C which has a slope of 0.260. The slight difference in slope of 0.004 is an arbitrary difference as far as the experimental data are concerned, but is the difference calculated on the assumption that the slope was affected only by the change from  $\gamma$  to  $\delta$  iron at 1400°C.

### Thermodynamic Calculations

**FeO Activity:** Calculation of  $a_{\text{FeO}}$  from the experimental data requires the choice of a standard state of unit activity for FeO and data on the equilibrium constant for the reaction:

Fig. 7—Log  $p_{\text{CO}_2}/p_{\text{CO}}$  vs.  $10^4/T$  showing the field of stability of Fe-Si-O melts in equilibrium with solid Fe. Coordinates of the invariant points are tabulated below:

| Invariant Point* | Log $\frac{p_{\text{CO}_2}}{p_{\text{CO}}}$ | $\frac{\text{CO}_2}{\text{CO}}$ | $\frac{10^4}{T}$ | Temperature, °C |
|------------------|---------------------------------------------|---------------------------------|------------------|-----------------|
| NJ               | -0.550                                      | 0.282                           | 6.08             | 1371            |
| 4                | -0.480                                      | 0.331                           | 6.91             | 1175            |
| 5                | -0.724                                      | 0.189                           | 6.88             | 1180            |
| D                | -1.118                                      | 0.076                           | 5.55             | 1530            |
| C                | -0.685                                      | 0.206                           | 5.57             | 1524            |

\* Labeling of points follows Darken and Gurry<sup>4</sup> and Darken.<sup>5</sup>

Similarly, the relation of  $a_{\text{FeO}}$  to temperature for slags saturated with  $\gamma$ -iron and  $\text{SiO}_2$  is found, combining eq 9 and 13:

$$\log a_{\text{FeO}} = \frac{300}{T} - 0.590 \quad [15]$$

In Table Vc, the values of  $a_{\text{FeO}}$  calculated by this equation are given for comparison with the experimental values. Extrapolating the data to the melting point of iron by means of the equation gives  $a_{\text{FeO}} = 0.377$  for silica-saturated iron-silicate slags at  $1530^\circ\text{C}$ . This figure is in good agreement with the value of 0.39 found at  $1600^\circ\text{C}$  by Chipman and Gokcen,<sup>13</sup> and both the newer figures are a little higher than an estimate of about 0.33 based on Körber and Olson's work.<sup>14</sup>

Fig. 8 shows graphically the variation of  $a_{\text{FeO}}$  with weight pct  $\text{SiO}_2$ . One curve adequately represents the results for all the temperatures investigated since, as already discussed, no variation of  $a_{\text{FeO}}$  with temperature was established within experimental error. For comparison, a dotted curve is given, showing how  $a_{\text{FeO}}$  would vary with pct  $\text{SiO}_2$  if the slags were ideal binary solutions of FeO and  $\text{SiO}_2$ . It should be noted that the curves also represent

Fig. 8—Variation of  $a_{\text{FeO}}$  with percent  $\text{SiO}_2$ .

oxygen activity, if  $a_o = 1$  for the 0 pct  $\text{SiO}_2$  melt, because  $a_{\text{Fe}}$  is constant for the system and  $a_{\text{FeO}} \propto a_{\text{Fe}} \times a_o$ .

**FeO- $\text{SiO}_2$  Constitution Diagram:** The FeO-activity data in Table V and Fig. 8 can be used to locate the liquidus curves for wüstite and silica in the FeO- $\text{SiO}_2$  constitution diagram. For each of the seven temperatures of wüstite-saturation measurements in Table Vb, the corresponding pct  $\text{SiO}_2$  in the melt is found from the activity curve in Fig. 8 as the abscissa corresponding to the measured value of  $a_{\text{FeO}}$  for wüstite saturation at this temperature. Similarly, the values of pct  $\text{SiO}_2$  in the melt for  $\text{SiO}_2$  saturation are found from Fig. 8 and Table Vc. The  $\text{SiO}_2$  percentages read from Fig. 8 in this way are given in parentheses in Tables Vb and Vc.

In Fig. 9 the results of the present investigation are compared with those of Bowen and Schairer. It should be kept in mind that this diagram is not a true binary diagram. Also, Fig. 9 differs from the familiar published diagram of Bowen and Schairer in that the abscissa is actual weight pct  $\text{SiO}_2$  as determined by analysis. It can be seen that the results of the present investigation agree well with the previous results of Bowen and Schairer.

**$\text{SiO}_2$  Activity:** Activities of  $\text{SiO}_2$  can be calculated by a Gibbs-Duhem integration. Taking the components of the slags as Fe, O, and  $\text{SiO}_2$ :

$$N_o d \log a_o + N_{\text{SiO}_2} d \log a_{\text{SiO}_2} + N_{\text{Fe}} d \log a_{\text{Fe}} = 0 \quad [16]$$

The third term drops out for the slags studied in this work because  $a_{\text{Fe}}$  is constant. Also, because  $a_{\text{Fe}}$  is constant,  $d \log a_o = d \log a_{\text{FeO}}$ . Hence, the Gibbs-Duhem equation becomes:

$$N_o d \log a_{\text{FeO}} + N_{\text{SiO}_2} d \log a_{\text{SiO}_2} = 0 \quad [17]$$

Integrating:

$$\log a_{\text{SiO}_2} = - \int \frac{N_o}{N_{\text{SiO}_2}} d \log a_{\text{FeO}} \quad [18]$$

Taking solid silica (tridymite) as the standard state for which  $a_{\text{SiO}_2} = 1$ , this integration has been carried out for the whole range of slag compositions at an arbitrarily chosen temperature of  $1350^\circ\text{C}$ . Data for the integration are tabulated in Table VI, and the activities of FeO and  $\text{SiO}_2$  are plotted against  $N_{\text{SiO}_2}$  in Fig. 10. The dashed curves indicate the behavior to be expected if the slags were binary solutions of FeO (so that  $n_o = n_{\text{Fe}} = n_{\text{FeO}}$ ) and  $\text{SiO}_2$  and

\* Values in parentheses calculated from:

$$\log a_{\text{FeO}} = - \frac{1790}{T} + 1.089$$

\*\* Values in parentheses calculated from:

$$\log a_{\text{FeO}} = \frac{300}{T} - 0.590$$

† Based on previous work; see Table IV.

Fig. 9—Constitution diagram showing liquidus data for iron-silicate slags in equilibrium with solid Fe.

if the activities were directly proportional to mol fractions. The hypothetical curve for  $a_{FeO}$  is based on the assumption that  $a_{FeO}$  equals mol fraction of FeO in the binary, while the hypothetical curve for  $a_{SiO_2}$  is based on the assumptions that  $a_{SiO_2} = 1$  for silica saturation and that  $a_{SiO_2}$  is proportional to mol fraction  $SiO_2$  calculated on the binary basis. The relative positions of the actual activity curves and the hypothetical binary curves show that the behavior of the system does not even approximate that of an ideal binary solution of FeO and  $SiO_2$ .

**Heats of Solution:** The partial molal heat content of a substance in solution, relative to the standard state of that substance, is readily calculated from data giving the variation of the activity of that substance with temperature for the solution of given constant composition. For a ternary system, the relative partial molal heat content of one component,  $\bar{L}_1$ , is given by:

$$\bar{L}_1 = R \left( \frac{\partial \ln f_1}{\partial \left( \frac{1}{T} \right)} \right)_{N_1, \frac{N_2}{N_3}} - R \left( \frac{\partial \ln f_1^\circ}{\partial \left( \frac{1}{T} \right)} \right)_{N_1, \frac{N_2}{N_3}} \quad [19]$$

in which  $R$  is the gas constant,  $T$  is the absolute temperature, and  $f_1$  and  $f_1^\circ$  represent the fugacities of the substance in the solution and in the standard state, respectively. Since  $a_1 = f_1/f_1^\circ$ , eq 19 ordinarily reduces to:

$$\bar{L}_1 = R \left( \frac{\partial \ln a_1}{\partial \left( \frac{1}{T} \right)} \right)_{N_1, \frac{N_2}{N_3}} \quad [20]$$

However, the activity-temperature data of the present investigation cannot be used directly with eq 20 because both the standard state of FeO and all the slags studied were solutions whose compositions varied with temperature to meet the condition of saturation with solid iron. The following approximation can be used to estimate the partial molal heat content of FeO in the slag relative to that in the pure Fe-O melt in equilibrium with solid iron.

$$\bar{L}_{FeO} = R \left( \frac{\partial \ln a_{FeO}}{\partial \left( \frac{1}{T} \right)} \right)_{N_{SiO_2}, \frac{N_O}{N_{Fe}}} = \text{approximately} \quad R \left( \frac{\partial \ln a_{FeO}}{\partial \left( \frac{1}{T} \right)} \right)_{N_{SiO_2}, a_{FeO} = 1} \quad [21]$$

Since experimentally it was found that  $a_{FeO}$  does not

Fig. 10— $a_{FeO}$  and  $a_{SiO_2}$  vs.  $N_{SiO_2}$  for Fe-saturated iron-silicate slags.

vary with temperature for given  $N_{SiO_2}$  in Fe-saturated slags, eq 21 leads to the result:

$$\bar{L}_{FeO} = 0$$

over the whole range of slag compositions. The probable error in  $\bar{L}_{FeO}$  from the experimental data is estimated to be  $\pm 400$  cal.

By applying the methods of partial differential calculus the error in eq 21 can be related to: 1—The rate of change of  $a_{FeO}$  with  $N_O/N_{Fe}$  at constant temperature, and 2—the rate of change of  $N_O/N_{Fe}$  with temperature for Fe saturation. Estimates of these two rates based mainly on Darken and Gurry's data indicate that the error in the approximate eq 21 probably is under 1000 cal per mol. This error is thus of the same order of magnitude as the experimental error.

Estimates of heats of solution of  $O_2$  and Fe cannot be made satisfactorily from the experimental data on Fe-saturated slags, and must await further data on the effect of  $N_O/N_{Fe}$  on  $a_{Fe}$  and  $p_{O_2}$ .

The partial molal heat content of  $SiO_2$  relative to the solid can be estimated by an approximation similar to that used in estimating  $\bar{L}_{FeO}$ :

$$\bar{L}_{SiO_2} = R \left( \frac{\partial \ln a_{SiO_2}}{\partial \left( \frac{1}{T} \right)} \right)_{N_{SiO_2}, \frac{N_O}{N_{Fe}}} = \text{approximately} \quad R \left( \frac{\partial \ln a_{SiO_2}}{\partial \left( \frac{1}{T} \right)} \right)_{N_{SiO_2}, a_{Fe} = 1} \quad [22]$$

Applying the principles of partial differentiation, the right-hand number of eq 22 can be written:

$$R \left( \frac{\partial \ln a_{SiO_2}}{\partial \left( \frac{1}{T} \right)} \right)_{N_{SiO_2}, a_{Fe}} = R \left( \frac{\partial \ln a_{SiO_2}}{\partial \ln a_{FeO}} \right)_{T, a_{Fe}} \left[ \left( \frac{\partial \ln a_{FeO}}{\partial \left( \frac{1}{T} \right)} \right)_{N_{SiO_2}, a_{Fe}} - \left( \frac{\partial \ln a_{FeO}}{\partial \left( \frac{1}{T} \right)} \right)_{a_{SiO_2}, a_{Fe}} \right] \quad [23]$$

The Gibbs-Duhem relation for the system, eq 17 gives:

$$\left( \frac{\partial \ln a_{SiO_2}}{\partial \ln a_{FeO}} \right)_{T, a_{Fe} = 1} = - \frac{N_O}{N_{SiO_2}} \quad [24]$$

Experimentally it was found that:

$$\left( \frac{\partial \ln a_{FeO}}{\partial \left( \frac{1}{T} \right)} \right)_{N_{SiO_2}, a_{Fe} = 1} = 0 \quad [25]$$

| 0                          | 0                  | $\infty$                        | 0.000                 | $-\infty$               | 0.000              |

\* Figures in first four columns are based on data taken from Table V for temperatures ranging from  $1352^\circ$  to  $1373^\circ\text{C}$ . Values of  $\log a_{\text{SiO}_2}$  in the fifth column were obtained by graphical integration, using a large plot of  $\log a_{\text{FeO}}$  vs.  $N_{\text{O}}:N_{\text{SiO}_2}$ .

The experimental data for  $\text{SiO}_2$ -saturated slags, as represented by eq 15, give:

$$\left( \frac{\partial \log_{10} a_{\text{FeO}}}{\partial \left( \frac{1}{T} \right)} \right)_{a_{\text{SiO}_2}=1, a_{\text{Fe}}=1} = 300 \quad [26]$$

Substituting eqs 24, 25, and 26 into eq 23, and using an average value of  $N_{\text{O}}/N_{\text{SiO}_2} = 1.3$  for  $\text{SiO}_2$ -saturated slags, the partial molal heat content of the  $\text{SiO}_2$  in  $\text{SiO}_2$ -saturated slags relative to the heat content of solid  $\text{SiO}_2$  is found:

$$\bar{L}_{\text{SiO}_2 (\text{solid})} = \text{approximately} + 1700 \text{ cal}$$

This figure is about the same as the heat of fusion of silica, so that within the combined experimental and estimation error, the partial molal heat of solution of liquid  $\text{SiO}_2$  in silica and iron-saturated slag appears to be nil. Since both  $\bar{L}_{\text{SiO}_2 (\text{liq.})}$  and  $\bar{L}_{\text{FeO} (\text{liq.})}$  are estimated to be nil, it follows that the heat of formation of the liquid slag from liquid  $\text{SiO}_2$  and liquid  $\text{FeO}$ , that is, the heat of mixing, is nil.

**Constitution of Iron-Silicate Slags:** Several attempts have been made to interpret the thermodynamic data in terms of constitution models of the slag. By far the best fit has been obtained by an ionic theory of slag constitution, similar in broad lines to that proposed by Chipman and Chang<sup>15</sup> to interpret the behavior of liquid iron oxides. However, this theory requires further development and can well await the availability of additional data from work now in progress on a wider range of slag compositions in the ternary system  $\text{FeO-Fe}_2\text{O}_3\text{-SiO}_2$ .

### Summary

The oxygen activities of liquid iron-silicate slags in equilibrium with  $\gamma$ -iron, ranging in composition from 0 pct to about 40 pct  $\text{SiO}_2$  (silica-saturation), have been determined at temperatures from  $1250^\circ$  to  $1400^\circ\text{C}$ . The experimental method consisted in bubbling  $\text{CO}_2\text{-CO}$  mixtures through the slags contained in iron crucibles. Compositions of incoming and outgoing gases were compared as a test of equilibrium, and the composition of the incoming gas was adjusted until equilibrium was attained. Equilibrium determinations were also made for the system slag: $\gamma$ -iron:wüstite:gas and for the system slag: $\gamma$ -iron:silica:gas.

The experimental results have been carefully correlated with the previous work of Bowen and Schairer on the same system, with the results of Darken and Gurry on the iron-oxygen system, and

with the work of Darken on the  $\text{Fe-Si-O}$  system. The results of the present investigation were found to be consistent with the previous work and thus indirectly afford some confirmation of the findings of the earlier investigation cited. These correlations are summarized in Figs. 7 and 9, which describe the system of iron-saturated, iron silicate slags in terms of the oxygen-activity temperature relationships and the constitution diagram, respectively.

From the experimental data, activities of  $\text{FeO}$  and  $\text{SiO}_2$  were calculated. It was found that the activity-composition relationships deviate considerably from those to be expected for an ideal binary solution of  $\text{FeO}$  and  $\text{SiO}_2$ . However, the partial molal heat of solution of  $\text{FeO}$  from the liquid iron-oxide melt in equilibrium with solid iron into the slags was estimated from the activity-temperature data to be zero. Also, the partial molal heat of solution of liquid silica (metastable) in silica-saturated slags was estimated to be zero.

## Some Notes on the Barley Shell Structure in Iron-Silicon Alloys

by R. V. Riley

IN the metallographic examination of the alloys of iron and silicon, several investigators<sup>1-7</sup> have reported on the occurrence of an unusual type of etched structure, particularly in the alloys of higher silicon content. This, the so-called "barley shell" structure, has been observed with iron-silicon alloys over a wide range of silicon content, and under certain circumstances it can be seen upon the micro-sections of pure iron.

The barley shell structure may be demonstrated most easily with iron-silicon alloys in the range 8 to 20 pct Si after etching in a hydrofluoric acid base etchant. Two etchants which produce the structure are: Corson's reagent, which is 2 parts hydrofluoric acid, 1 part nitric acid, and 2 parts glycerol; and picric acid reagent, which is 1 part hydrofluoric acid and 1 part saturated solution of picric acid in alcohol. Both when freshly prepared and used for etching commercial silicon-iron alloys containing 14 to 16 pct Si, invariably produce the barley shell structure shown in Fig. 1a. It is now well known that the barley shell structure is a pseudomorph and the true structure of an alloy of this composition consists of a single phase of silico-ferrite together with graphite as shown in Fig. 1b.

Lower silicon alloys and even pure electrolytic iron may also be etched in the above reagents to give the barley shell provided the etchant has been either: 1—Stored in contact with glass or silica, or 2—used previously for etching an iron containing silicon.

Pure iron etched in perfectly pure hydrofluoric acid base etchants free from silicon contamination gives a normal structure free from the barley shells. Therefore, although the hydrofluoric acid in the reagent primarily is responsible for the barley shells, silicon, or its compounds, also must be present, either in the etching reagent or in the specimen.

It was of considerable interest to the author to read the paper by Wachtell,<sup>7</sup> in which the barley shell etch was deliberately used for the identification of the boundaries of high and low silicon areas in diffusion experiments made upon laminate bars or compacted and sintered pure iron and ferrosilicon powders. This method of utilizing the barley shell etch is novel and in the hands of the investigator gave a useful differentiation between the high and low silicon areas in those specimens. For the reasons already given, however, the technique is not to be regarded as of universal application. Misleading results might be obtained, for example, if two or more specimens were etched in the same etchant. Fresh pure reagents only must be used each time. Provided this is done and the investigators are well aware of the limitations of the

Fig. 1a (upper)—Barley shell structure in commercial 15 pct Si-Fe alloy.

Fig. 1b (lower)—True structure of silico-ferrite and graphite in commercial 15 pct Si-Fe alloy.

X600. Area reduced approximately 50 pct for reproduction.

method, then the barley shell pseudomorph can be made of limited use in distinguishing between higher and lower silicon areas in a microspecimen of a ferrous material. The greatest of care must be exercised in the interpretation of the results which may be regarded as qualitative only and may, in fact, not be specific to silicon alloys.

# Metallurgy of Cobalt Production

## From Cupriferous Pyrite

by Sanai Nakabe

Japanese wartime economy demanded domestic cobalt production. This paper describes a process operated for two years at the Besshi mine and smelter on extremely low grade (0.1 pct Co) pyrite concentrates obtained from copper ore. The steps in the process were roasting, leaching, precipitation, reduction fusion to crude cobalt, and finally refining by electrolysis to 99+ pct.

COBALT ore deposits in Japan are all small and of poor grade. In the past, a small amount of cobalt has been produced from the best portions of a few of these deposits, and very little production is expected in the future. In addition to these lean cobalt ores, cobalt is present in the cupriferous pyrite which is fairly abundant although of low grade, as is shown in Table I. Considerable cobalt is expected from these deposits because of their extent.

Cobalt cannot be exclusively recovered economically from ore of this type; however, if means could be devised to recover it as a byproduct of copper production, a fairly large production at reasonable cost could be expected from Japanese sources. It was along this line that the research work was done.

### Selection of Suitable Process

The process for extracting cobalt differs from ore to ore according to their composition. The difficulty in cobalt metallurgy arises from the fact that chemically cobalt resembles many such common metals as Mn, Fe, Ni, Cu, and Zn, associated with it in the ores. In the present case the most serious difficulties were:

- 1—Extremely low grade ore, 0.1 pct Co.
- 2—The large proportion of iron accompanying

SANAI NAKABE, Member AIME, is Chief Engineer, Besshi Mining Co., Ltd., Tokyo, Japan.

cobalt and its close similarity in chemical behavior.

3—The fairly large proportion of zinc and manganese and their chemical similarity to cobalt.

The recovery of cobalt oxide as a byproduct of the hydrometallurgy of copper had been attempted in Japan but was stopped after a short period because it proved uneconomical. The literature disclosed no method for the recovery of cobalt from cobaltiferous copper pyrite and it was therefore necessary to devise a new process.

The following basic principles were considered in selecting the process:

1—A major alteration in copper production methods should not be necessary.

2—The first step should be the extraction of cobalt leaving the large quantity of iron unaffected. For this purpose wet metallurgy would be preferred.

Table II. Distribution of Cobalt to Intermediates in Copper Smelting

|                     | Cu,<br>Pct | Fe,<br>Pct | Co,<br>Pct | S,<br>Pct | Co<br>Quantity |
|---------------------|------------|------------|------------|-----------|----------------|
| Crude ore           | 1.17       | 19.16      | 0.03       | 9.98      | 100            |

| Blast furnace matte | 35         | 40         | 0.3        | 23        | 20             |
| Blast furnace slag  | 0.3        | 35         | 0.06       |           | 35             |
| Converter slag      | 2          | 55         | 0.4        |           | 20             |
| Blister copper      | 98         |            | 0.002      |           | 0.1            |

3—A crude precipitate of cobalt would be satisfactory in order to avoid a large expenditure in chemically treating a huge volume of leach solution to obtain a pure precipitate.

4—The crude cobalt precipitate would be further refined. It would not matter if the process became somewhat complicated at this point because the quantity of material for treatment would be decreased markedly.

### Selection of Direct Raw Material

As the raw material it was first necessary to select an intermediate product from the copper extraction process. Four were selected, namely, pyrite concentrate from the flotation, matte from the blast furnace, slag from the same, and slag from the converter.

Three different processes were devised for treating concentrate, matte, and slag. The first one for treating the concentrate proved to be best suited for the circumstances at Besshi mine and the Japanese wartime economy. This process was operated on a plant scale and will be reported here, but the other two were not developed to plant size although they proved to be valuable in those cases where somewhat more cobalt is contained in the raw material in copper smelting. The compositions of several intermediate products at the Besshi smelter are shown in Table II. In order to make it pay it is desirable that a process for treating a poor raw material should have some extra merits in addition to the principal one which, in this case, aims at cobalt recovery. By treating iron concentrate, a quantity of copper would be recovered and, at the same time, the quality of the leached residue, by the elimination of copper, would be enhanced.

### Flotation

Usually no distinct cobalt mineral is identified in the ores and it is supposed that cobalt exists in solid solution in the pyrite crystal, displacing some of the iron atoms. Whether there is any difference in cobalt content between chalcopyrite and iron pyrite is open to question. In the case of the Besshi ore there is little difference according to the analyses of the two kinds of concentrate produced at the flotation mill, Table III. It was concluded therefore that no change in the process of flotation was necessary and both

concentrates must be treated separately for cobalt production.

### Roasting

Various methods were examined to render cobalt in pyrite soluble in water or dilute acid, and it was finally decided that an oxidizing roast was the best practical method if sufficient attention was paid to operation. Roasting for sulphuric acid production needs no special regulation, but for cobalt extraction careful control in roasting is necessary. The most important factor in roasting regulation is the temperature control which will be explained.

Practically all of the soluble cobalt in the cinder proved to be cobalt sulphate and not oxide. This was true with acid leaching as well as with water leaching not only for oxidizing roasts but for all the roasting methods tried. Therefore, it was most desirable to convert as much into sulphate as possible. Most of the cobalt sulphate was formed near the final roasting stage according to the numerical order of the following equations. An example of the successive change is given in Table IV which shows analyses of samples taken from each hearth of a Herreshof-type roaster. The diameter of each of the eight hearths was 9 ft 6 in.

Cobalt sulphate was not formed in the rapid oxidation of pyrite resulting in a black cinder. One of

the necessary conditions, therefore, was slow oxidation through control of the temperature or air supply. This resulted in a brown cinder. Another factor was the formation of ferrite. In the presence of ferric oxide, ferrite formation begins at about 600°C and increases as the temperature rises. However, in the presence of ferrous oxide and no ferric oxide, ferrite does not form even at the high temperature of 800°C. Table V shows the formation of ferrite when a finely ground mixture of 1.5 g of Fe<sub>2</sub>O<sub>3</sub> and 1.5 g of CoSO<sub>4</sub> · 7H<sub>2</sub>O was heated for 1 hr at the indicated temperatures. The results are shown of leaching 1 g of the product in water and further leaching the residue in boiling 2 pct H<sub>2</sub>SO<sub>4</sub>. Table VI indicates the absence of ferrite formation when a similar experiment was conducted using ferrous oxide instead of ferric oxide.

The optimum roasting temperature for cobalt sulphate formation was found to be about 550°C. This was determined experimentally, Table VII, using a small electrically heated rotary kiln. The rate of formation of cobalt sulphate is low and many hours are required for a satisfactory conversion. This is shown in Table VIII which summarizes the best results obtained by leaching cinder from different furnaces. Thermal decomposition of cobalt sulphate is not appreciable at temperatures below 750° to 850°C.

In practice a Herreshof-type furnace was found best suited for the purpose. The charging rate and the air supply must be so controlled as to obtain a gradual and sufficient oxidation, and at least two of the upper hearths must be maintained at 500° to 600°C. The maximum temperature of the upper hearths usually went over 800°C but this was not detrimental to cobalt sulphate formation in the absence of Fe<sub>2</sub>O<sub>3</sub>. The conversion was about 70 pct (soluble Co 0.09 pct) under good conditions, but fell below 30 pct with poor regulation. The ore particles swelled, becoming very porous, which had a favorable effect on leaching, Table IX. The moistures of cakes obtained by vacuum filtration of slurries are shown to give a rough idea of the porosity of the particles.

Leaching

The purpose of leaching is to dissolve cobalt and copper, leaving all of the iron undissolved in the residue. The only economical solvents, in view of the

poor grade of the raw material, would be water or dilute acid. It was concluded, after thorough experimenting, that even dilute acid was not suitable because, although it gave slightly better cobalt and copper extraction, it dissolved considerably more iron than was the case with water leaching. Grinding, heat, and increased leaching time had little effect, as shown in Tables X through XIV. Sea water could also be used, Table XV.

Cinder was classified into three parts as indicated in Table XIV, and half of each ground to —100 mesh. Both halves were water-leached for comparison.

The data in Tables X to XV lead to the conclusion that the leaching is a very simple problem, but in practice it is very important to wash the residue efficiently in order to obtain simultaneously high extraction and high concentration of the leach solution. Continuous countercurrent decantation was adopted easily because of the fine particle size. High porosity of the cinder was not conducive to good washing because in a thickener the settled material contains as much as 40 to 50 pct water. The analysis of the leach solution was as follows: Co, 0.2 to 0.3; Cu, 0.5 to 1.5; Fe, 0.3 to 1.5; Zn, 0.3 to 0.6; Mn, 0.1 to 0.2 g per liter.

Treatment of Solution in General

Recovery of pure cobalt oxide from such a solution is difficult for a variety of reasons. The cobalt concentration is small and any prior removal of copper and iron by any of the usual methods would still leave enough behind to seriously contaminate the cobalt when ultimately recovered. Moreover, extreme dilution made necessary the treatment of such huge quantities of solution that production cost inevitably would be high in the case of a complicated flowsheet involving heating, filtration, reagents, etc. Zinc and manganese are so close to cobalt in chem-

\* Water leaching at 60° for 30 min.

ical behavior that their elimination or separation is difficult even in the case of chemical analysis. No known hydrometallurgical method was entirely satisfactory from a technical and economic viewpoint.

It was decided finally to treat the leach solution to obtain a cobalt precipitate after eliminating only those easily separable elements to such a degree as could be accomplished easily. This means that the solution treatment would be a mere concentrating process differing from the usual hydrometallurgical process in which refining is accomplished.

The simplest operation in each step in the process was chosen; heat was not involved, separation of the bulk of the liquid from any precipitate was by decantation, and the whole was operated continuously so that huge volumes of liquid could be passed through small equipment. Chemical reactions were selected that could be adapted to such a flowsheet. Equipment consisted of small agitation tanks for reagents, one or two medium tanks for completion of reactions, a large Dorr thickener for decantation, and filter presses to take only thickened slurry when necessary. Such cheap and simple steps were arranged for each individual reaction.

### Elimination of Copper and Iron

The simplicity of the equipment referred to above required a precipitate that would settle easily at room temperature, namely one of fairly large particle size. To achieve this in minimum time it was necessary to consider the solubility product of the precipitate to be formed. Copper sulphide or ferric hydroxide, for example, are not suitable because their solubility products are too small to allow the precipitates to coagulate or grow to larger particles. Of course coagulation could be accomplished by applying heat and controlling the pH, but these procedures were out of the question. Since, on the other hand, a high solubility product meant incomplete elimination, there was no alternative but to choose precipitates having a moderate solubility product. In addition the solubility product of the copper or iron precipitate must be low in comparison with that of the cobalt compound present to allow separation. These requirements led to the selection of eliminating copper as the hydroxide.

Regarding the iron, there were many reasons for precipitating it as the hydroxide. Iron was present in the solution as ferrous sulphate. The solubility product of ferric hydroxide was too low, as men-

tioned earlier, and any excess of reagent used for oxidizing ferrous iron is apt to precipitate  $\text{Co}(\text{OH})_2$  together with the iron. Furthermore, ferric hydroxide has a greater tendency to drag down cobalt by occlusion. In the process iron and copper were successfully eliminated simultaneously as  $\text{Fe}(\text{OH})_2$  and  $\text{Cu}(\text{OH})_2$ .

Table XVI shows the results of experiments in which varying amounts of soda ash were used for precipitation.

The following comments are important from the standpoint of practical operation:

1—Loss of cobalt is closely related to the excessive elimination of copper from solution.

2—Loss of cobalt increases with increase of iron in the original solution.

3—The elimination of copper and iron must be made in two stages in order to diminish their concentrations below 0.01 g per liter, which means the remaining copper or iron must be less than 1/20th of the cobalt, thus limiting the loss of cobalt to a few percent.

4—The precipitate from the second stage contains considerable cobalt which must be recovered. To do this the thickened slurry is agitated with the original solution in the first agitator where the cobalt is dissolved, Table XVII, according to the following reaction:

This simple method is very effective in saving reagents because the second stage precipitate is not only leached without consuming any particular reagents, but also serves as a base for precipitating copper from the original solution.

Composition of original solution added: Cu 1.05, Co 0.32, Fe 0.05 g per liter. To 100 cc of second copper precipitate slurry, the sulphuric acid or original solution was added, agitated for 30 min at room temperature and filtered. Before treatment 100 cc of second copper precipitate contained the following: Dry material, 1.2 g; Co, 0.024 g; Cu, 0.394 g; and Fe, 0.003 g.

5—Soda ash additions were controlled using the remaining  $\text{CuSO}_4$  in the mother liquor as indicator, 0.1 g per liter in the first stage and 0.01 g per liter in the second. The copper present was determined colorimetrically by the operator. In actual operation

Table XV. Comparison of Fresh and Sea Water for Leaching

| Medium          | Co, Pct | Cu, Pct | Fe, Pct |
|-----------------|---------|---------|---------|
| Distilled water | 0.049   | 0.29    | 0.035   |
| Aqueduct water  | 0.049   | 0.29    | 0.029   |
| Sea water       | 0.048   | 0.26    | 0.006   |

the consumption of soda ash was about three times as much in the first stage as in the second.

6—The two-stage elimination of copper and iron was necessary also because, in spite of the large storage tank, the concentration of the feed solution varied considerably, 0.6 to 1.3 g per liter Cu, and with continuous treatment the addition of the correct amount of soda ash was impossible. Therefore, the first addition was purposely somewhat insufficient so that an unexpected decrease of copper in the feed solution would not result in an increase of cobalt in the precipitate. On the other hand, the second soda ash addition was maintained in excess so that a sudden increase of copper would not result in its incomplete elimination.

7—Soda ash was chosen as the precipitant although, from a reagent cost standpoint, milk of lime had some advantage. However, there are some disadvantages in using lime. Calcium sulphate crystallizes on the inner surfaces of pumps, pipes, and tanks making it necessary to use launders for solution transfer and to so place tanks that the transfer can be done by gravity decantation, thus eliminating pumps. Also if there are coarse particles of lime in the reagent there will be excessive precipitation of cobalt in their vicinity. It is preferable to use lime immediately after slaking.

8—The precipitate had the following analysis: Cu, 25 to 35 pct; Fe, 15 to 25 pct; Co, 0.2 to 0.3 pct; and Zn, 2 to 4 pct. This material could be charged into the blast furnace for copper recovery.

Precipitation of Cobalt

Cobalt was precipitated as cobaltic hydroxide using soda ash and chlorine. The chlorine which was purchased as a liquid was introduced into the solution as fine bubbles through porous porcelain tubes. In this process the separation of manganese was difficult since it precipitated as MnO<sub>2</sub> together with the cobalt. Part of the manganese was oxidized to permanganate, coloring the solution. Some zinc is also precipitated along with the cobalt.

The soda and chlorine additions were so regulated as to maintain a pH of 5.0 to 5.5 and an excess of chlorine, including MnO<sub>2</sub> and ClO<sub>2</sub>, of 0.05 to 0.1 g per liter. The pH was determined with test papers and the free chlorine by simplified permanganometry, both tests being made on the job. Lime cannot be substituted for soda ash in this process since the calcium sulphate thus formed accompanies the cobalt precipitate which in the subsequent reduction process yields cobalt sulphide instead of the desired metallic cobalt. Although the cobalt precipitate obtained was impure the process did serve to produce a concentrate from the dilute leach solution. The analysis of the precipitate was: Co, 30 to 35 pct; Cu, 0.5 to 1.0 pct; Fe, 0.5 to 1.0 pct; Zn, 2 to 8 pct; and Mn, 5 to 8 pct.

Reduction of Cobalt Precipitate

The dried precipitate was mixed with coke breeze and flux and melted in a small electric arc furnace. Crude metallic cobalt containing copper and iron was obtained, the manganese was slagged off, and the zinc was eliminated by vaporization. The crude cobalt containing about 90 pct Co, 2 to 5 pct each of Cu and Fe, 0.5 to 1.5 pct Ni, and traces of Mn and Zn, was refined electrolytically.

In the reduction the chemical similarity of the oxides of cobalt and manganese made it necessary to operate in two stages to eliminate manganese. The first stage was a reducing fusion wherein all of the cobalt and a small amount of the manganese were reduced. The second stage was an oxidizing fusion wherein the manganese was oxidized into the slag by the addition of crude cobalt precipitate. This eliminated the manganese but gave a slag containing cobalt which was recovered by returning the slag to the first stage. The degree of reduction and oxidation in the two stages was adjusted according to the cobalt content of the slag as shown in Table XVIII, based on a study of the equilibrium, Table XIX. The corresponding alloys and slags were obtained by melting CoO, MnO<sub>2</sub>, charcoal, and siliceous sand in various proportions in a crucible over an oxygen-coal gas burner.

Electrolysis

The literature on the electrolytic refining of cobalt is scanty and many details remain to be studied. Nevertheless, pure metallic cobalt was commercially produced by the electrolytic process here described.

The electrolyte was held to about 30 g Co per liter and the sulphate and ammonium ion concentrations regulated to correspond to a nearly equimolecular mixture of cobalt sulphate and cobalt ammonium sulphate. The pH of the solution was maintained at 5.5 after purification, since lower values made it difficult to eliminate iron and higher values gave a

Manganese in the anodes will go into solution where it remains, but zinc will deposit, necessitating complete removal of the latter at the anode furnace.

The pilot plant was operated during 1941 and the commercial plant design was started in 1942. It was decided that the capacity should be 300 tons of pyrite concentrate per day which was the tonnage expected from the Besshi mine. The most serious

problem was the selection of corrosion resistant materials. Acid was not to be used which helped somewhat, however, the corrosive action of copper sulphate and the erosion by the ore slurry was still a difficult combination to overcome. Cupro-nickel or 18-8 stainless steel were best suited, but they were in scarce supply. Consequently tanks, pipes, and air lift pumps were made of reinforced concrete. A few parts including an air nozzle were made of 13 pct Cr steel. Launderers and agitator were made of wood, and pumps were of bronze or hard lead. All equipment except the roasting furnace was made on the job. Construction started in August 1942 and was completed in August 1943 at a cost of about 1,000,000 yen. Arrangement of the main equipment is indicated in Fig. 1.

### Commercial Operation

The operation was started in September 1943 and continued successfully until the surrender in 1945. The quantities treated and produced and some examples of analyses of raw material, intermediate and final products are shown in Tables XX and XXI.

### Economics

The project was demanded by the war economy regardless of cost, but it represents a sincere effort on the part of the author to develop a process which would be profitable even in peace time. Indeed the operating cost under normal conditions estimated from the actual results show a cost less than the prewar price of cobalt. However, the actual cost calculated from the data of the short operating period was high owing to the high repair costs incurred by the small but numerous faults of the equipment in the early days of operation. In fact, the process was profitable even during the war in comparison with other plants in Japan upon whose costs the controlled price of cobalt was based. Further reduction in cost is anticipated by substituting milk of lime for most of the soda ash which is responsible for a large part of the cost, or by replacing chlorine and soda ash for cobalt precipitation with bleach solution produced by direct electrolysis of sea water.

### Summary

Metallic cobalt was obtained from cupriferous pyrite as a byproduct of copper production at Besshi

mine and smelter, Japan. The project was undertaken because, since the early thirties, it was necessary for Japan to be self-sufficient in cobalt. The research work started in 1939 and was finished in 1940. The pilot plant was operated in 1941 and the final plant produced cobalt from 1943 until the Japanese surrender in 1945. About 7 tons of metallic cobalt were produced from approximately 37,000 tons of pyrite cinder.

Owing to the extremely low grade of the ore (0.1 pct Co) it was difficult to make the project profitable, however this was accomplished by the process which is summarized as follows:

1—Iron pyrite concentrate, obtained as froth from the flotation mill after separating chalcopyrite, was treated for cobalt production. It was roasted for sulphuric acid production and then leached.

2—The leach solution, containing  $\text{CuSO}_4$ ,  $\text{FeSO}_4$ ,  $\text{ZnSO}_4$ , and  $\text{MnSO}_4$ , in addition to  $\text{CoSO}_4$ , was treated by a simple process to obtain a crude cobalt precipitate after a rough elimination of copper and iron. A complete refining of cobalt was not intended because of the expense of treating large quantities of solution by a complicated procedure.

3—Crude metallic cobalt was obtained from the precipitate by a reducing fusion which eliminated zinc and manganese whose removal would otherwise have been difficult.

4—The crude metallic cobalt was refined by electrolysis.

5—Because of shortages of construction material the whole process was designed to use few units of simple design and special stress was laid on this requirement during development.

### Acknowledgment

The author wishes to express his gratitude to S. Tanaka, President of Besshi Mining Co., Ltd., for permission to publish this paper; to E. Arakawa, former Managing Director and General Manager of Besshi Mining Office, and T. Matsuoka, formerly Superintendent of Niihama Flotation Mill, for their valuable technical suggestions; and to C. A. Knierim, Chief Chemist of the Baltimore Plant, American Smelting and Refining Co., for his collaboration with the author in preparing the paper for publication.

# Effects of Precompression On The Behavior of the Aluminum Alloy 24ST4 During Cyclic Direct Stressing

by S. I. Liu

THE effects of strain histories, consisting of several prestrains in opposite directions, on the flow and fracturing characteristics of metals determined in a final test have been investigated previously.<sup>1-3</sup> Such strain histories vary from a single prestrain in tension or compression to the number of strain cycles leading to fatigue failure.<sup>1</sup> Between these two limits, various strain histories could be visualized and some can be attained readily. One such example is a strain history consisting of a first prestrain in tension of various magnitudes and a second prestrain in compression also of various magnitudes.<sup>2</sup> In this investigation the strain history was extended to the combination of these two limits, i.e., a single prestrain in tension or compression followed by balanced strain cycles of a selected magnitude  $\epsilon_0 = \pm 0.12$ . It was found in this case that only compressive initial prestrains could be investigated with sufficient accuracy.\*

Such strain histories can be considered also as (low cycle) fatigue tests of a metal subjected to various amounts of cold working. It appears from previous publications that cold working within a wide range of reductions usually raises the unnotched fatigue strength of many metals.<sup>4-6</sup> This effect, however, has been found to be inconsistent and sometimes reversed for other metals.<sup>5,7</sup> Furthermore, Ludwik reports that the yield strength of cold-worked specimens may be reduced by cyclic strains, while that of materials without cold work is generally increased in the initial cycles.<sup>8,9</sup>

In addition to the above tests, a study was made of the effect of intermediate re-solution heat treatment on low cycle fatigue behavior. Such anneals should eliminate the strain hardening induced by the cyclic strains. As far as their effect on the fracture characteristics is concerned, a few previous tests seemed to indicate that the damage resulting from cyclic strains is retained only partially after heat treatment.<sup>10</sup>

A further investigation was made in which one specimen was subjected to repeated unbalanced tension cycles in which the strain interval was approximately  $+0.013$ . This repetition of plastic tension

S. I. LIU, Student Associate AIME, with Department of Metallurgy, Pei-Yang University, Tientsin, China, was with Metals Research Laboratory, Case Institute of Technology.

Discussion on this paper, TP 3065E may be sent, 2 copies, to AIME by Aug. 1, 1951. Manuscript, March 28, 1949; revision, Nov. 15, 1950. Detroit Meeting, October 1951.

This investigation is one of a series of reports in a research program conducted at the Metals Research Laboratory, Case Institute of Technology, Cleveland, in cooperation with The Office of Naval Research, U. S. Navy.

Fig. 2 (below)—Stress-strain curves for the precompressed aluminum alloy 24ST4 after various strain cycles at a strain of  $\epsilon_0 = \pm 0.12$ .

damages the material slightly. This result appears to confirm Ludwik's observations.<sup>8,9</sup>

Commercial  $3/4$ -in. rod of the aluminum alloy 24ST4 was selected for this investigation. The material was subjected to the following treatments before machining: 1—Re-solution treatment at  $920^\circ \pm 10^\circ\text{F}$  for 45 min, 2—water quench at room temperature, and 3—aging for four days at room temperature.<sup>†</sup> The treated material then was machined to desired specimen contour and tested. A coolant was used during machining to minimize any artificial aging effects of heating during machining. In some cases the 24ST4 specimens were reheat treated after having been strained. In these cases, the heat treatment was the same as the re-solution heat treatment described above.

## Procedure

As shown in Fig. 1, threaded end specimens with a minimum diameter of 0.266 in. and a contour radius of 2 in. were used for prestraining to an axial compressive strain ranging from  $\epsilon_p = -0.10$  to  $\epsilon_p = -0.48$ . For large prestrains, two consecutive com-

\* After a comparatively large initial tension and machining, necking no longer took place at the original minimum section.

† This alloy reportedly is stable as regards mechanical properties after a natural aging period of four days.

Fig. 3—Cyclic stress-strain characteristics of the aluminum alloy 24ST4 after various amounts of precompression.

pressions with an intermediate machining were applied, the amount of compressive strain performed in each single compression being kept below  $\epsilon_p = -0.30$  to avoid buckling. The precompressed specimen was machined to its initial contour and finally subjected to cyclic straining. Each strain cycle consisted of a first strain in tension  $\epsilon_1 = +0.12$  and a second strain in compression  $\epsilon_2 = -0.12$ . Such tension-compression strain cycles were carried on until fracture took place. To investigate the progressive change in fracturing characteristics, specimens were subjected to failure in tension after various numbers of cycles. As was pointed out before, no significant change in specimen contour was observed after each cycle.

The prestrains, the strain cycles, and the final testing all were done on a regular hydraulic 60,000-lb tensile machine. Concentricity during compression

was obtained by using a truncated-cone-shaped fixture attached to an antifriction die set and concentricity during tension, by using a specially designed fixture.<sup>11</sup> The change of diameter at the minimum section in either tension or compression was measured by means of a radial strain gage which measured changes in diameter directly to 0.0001 in.<sup>2</sup> The stress-strain relations for all strain cycles and all final tests thus obtained are presented in Figs. 2 to 12.

## Results

**Effects of Precompression on the Flow Characteristics during Cyclic Loading:** The changes in flow characteristics are illustrated in Figs. 2 to 5. Each family of curves in Fig. 2 corresponds to a given value of precompression, and each family consists of stress-strain curves obtained on specimens tested after various numbers of strain cycles. In Fig. 3, stress-strain curves for each given value of precompression were plotted in the sequence of straining, regardless of the difference in the signs of stresses and strains. In Fig. 4, each family of curves corresponds to a given number of cycles, and each family consists of stress-strain curves from specimens strained to various values of precompression before the given number of cycles. The stress required to perform the selected value of strain ( $\pm 0.12$ ), the true necking stress, and the conventional tensile strength are plotted in Figs. 5a and b, as functions of the number of cycles.

From Figs. 2 to 5, the following can be deduced regarding the effects of precompression on the flow characteristics:

1—Cyclic straining of a re-solution heat treated metal apparently creates two superimposed and counteracting effects; namely, strain hardening and deterioration. For a given magnitude of cyclic strain, strain hardening disappears after a certain number of cycles, while the deteriorating effect continues until a fatigue-type fracture takes place. As shown in Fig. 2, for the selected value of cyclic strain ( $\epsilon_0 = \pm 0.12$ ) the net effect of the first cycle could be either strain hardening or deterioration, depending upon the magnitude of the precompression. For small precompressions between 0.00 and  $-0.18$ , the effect of the first cycle is strain hardening and the amount of strain hardening decreases with increasing precompression; on the contrary, for large compressions between  $-0.3$  and  $-0.48$ , the net effect of the first cycle is deterioration as shown by the lowered stress-strain curves after the first cycle.

2—As shown in Figs. 3 and 4, as the number of

| Cyclic strain $\epsilon_0$           | = Either one of two limits of natural strain in a balanced strain cycle consisting of a first strain $\epsilon_1$ in tension and a second strain in compression $\epsilon_2$ , ( $\epsilon_2 = -\epsilon_1$ ). |
| Prestrain $\epsilon_p$               | = Prestrain in either tension (positive) or compression (negative).                                                                                                                                            |
| Fracture stress $S_f$                | = Load at fracture divided by the area at the minimum section at the moment of fracture.                                                                                                                       |
| Retained ductility $\epsilon_f$      | = Maximum natural strain after fracture.                                                                                                                                                                       |
| Number of cycles $N$                 | = Number of repetitions of strain cycles.                                                                                                                                                                      |
| Changes in fracture stress $(S_f)_n$ | = Change in fracture stress due to precompression only ( $n = \text{constant}$ ).                                                                                                                              |
| $(S_f)_p$                            | = Change in fracture stress due to strain cycles only ( $\epsilon_p = \text{constant}$ ).                                                                                                                      |
| Changes in retained ductility:       |                                                                                                                                                                                                                |
| $(\epsilon_f)_n$                     | = Change in retained ductility due to precompression only ( $n = \text{constant}$ ).                                                                                                                           |
| $(\epsilon_f)_p$                     | = Change in retained ductility due to strain cycles only ( $\epsilon_p = \text{constant}$ ).                                                                                                                   |

Fig. 4 (left)—Stress-strain curves for the precompressed aluminum alloy 24ST4 after various strain cycles at a strain of  $\epsilon_0 = \pm 0.12$ .

Fig. 5 (right)—Effect of precompression on the flow characteristics of the aluminum alloy 24-ST4 under cyclic straining at a strain of  $\epsilon_0 = \pm 0.12$ .

straining cycles increases, the stress-strain curves for various magnitudes of precompression approach each other. Moreover, a reversal of the order of strain hardening takes place after two cycles, i.e., the stress-strain curves after the first several cycles become lower than those of the first several cycles. These appear to be the results of the counteraction between strain hardening and deterioration.

3—As shown in Fig. 5, the stresses required to perform the desired cyclic strain, the necking stress, and the tensile strength all remain constant after the first cycle. The yield strength after large precompressions decreases slightly with increasing number of cycles.

**Effects of Precompression on the Fracturing Characteristics under Cyclic Straining:** The total strain history introduced in this investigation consisted of two parts: The precompression and the following strain cycles. In order to visualize the combined effects of both on the fracturing characteristics of the material, the individual effect of each part should be considered. Thus the following four quantities were introduced here for graphical representation of experimental results:

$(\epsilon_f)_n (S_f)_n$  = change in ductility and fracture stress due to precompression only ( $n$  = constant)

$(\epsilon_f)_p (S_f)_p$  = change in ductility and fracture stress due to strain cycles only ( $\epsilon_p$  = constant)

Fig. 6 (left)—Effect of strain cycles ( $\epsilon_0 = \pm 0.12$ ) on the fracturing characteristics of the aluminum alloy 24ST4 after various amounts of compressive prestrain.

Fig. 7 (right)—Effect of precompression on the fracturing characteristics of the aluminum alloy 24ST4 under cyclic straining at a strain of  $\epsilon_0 = \pm 0.12$ .

Fig. 8 (left)—Change in fracturing characteristics of precompressed aluminum alloy 24ST4 due to cyclic straining ( $\epsilon_0 = \pm 0.12$ ) as functions of the number of cycles.

Fig. 9 (right)—Change in fracture characteristics of the cyclically strained aluminum alloy 24ST4 ( $\epsilon_0 = \pm 0.12$ ) due to precompression as functions of the precompression.

precompression was increased by inserted strain cycles as shown in Fig. 9a.

Thus it appears that within the range of precompression and number of cycles investigated, each of these two factors, precompression and cyclic straining, causes a reduction in fracture stress of the material when acting alone; on the other hand, when acting together, the combined effect appears greater than the sum of the two individual effects.

3—The effects of precompression on the retained ductility after varying numbers of strain cycles were as follows:

(a) For precompressions at magnitudes greater than 0.10, the ductility of the virgin material was decreased with increasing precompression as shown in Fig. 6b and 7b.

(b) As shown in Fig. 6b, and the previous investigation,<sup>1</sup> the ductility of the material was decreased suddenly between the last cycle and the fatigue fracture. Fig. 8b shows that precompression increases the rate of such reduction in ductility and accelerates the approach of such a sudden reduction, i.e., accelerates the occurrence of fracture. However, the test data also show that except in the last cycle, the rate of reduction in ductility by cyclic straining was decreased by precompression.

4—The effects of strain cycles inserted between precompression and the final testing on the retained ductility for varying precompression were:

(a) The ductility of the virgin material was decreased with the increasing number of strain cycles as shown in Fig. 6b and 7b.

(b) The rate of change in ductility due to precompression was changed with the increasing number of inserted strain cycles. As shown in Fig. 9b for precompressions of magnitude greater than 0.10, the rate of reduction in ductility by precompression increases with increasing number of cycles.

Previous investigations showed that cold working in drawing or rolling up to very high reduction usually increased the unnotched strength of metals.<sup>4-6</sup>

This investigation, however, indicates that the effect of precompression is opposite to the effect of drawing or rolling. It previously was found in this laboratory and also by other authors, that prestrain in drawing or rolling increases, while prestrain in compression decreases, the fracture stress of many metals in the subsequent tensile test.<sup>3</sup> This finding appears to be in good agreement with the results of this investigation.

Effects of Intermediate Reheat Treatment† on Low Cycle Fatigue Behavior: Fig. 10 shows the stress-strain curves in tension up to fracture after different numbers of cycles, for specimens without intermediate re-solution heat treatment, specimens with intermediate re-solution heat treatment after each cycle, and specimens with only one re-solution heat treatment before the final testing. In this case, no precompression was used. The figure shows that even after re-solution heat treatment, the stress-

Fig. 10—Stress-strain curves for the aluminum alloy 24ST4 after cyclic straining at a strain of  $\epsilon_0 = \pm 0.12$  with and without inserted re-solution heat treatment, showing the permanent damage done by cyclic straining.

† In this series, the reheat treatment consisted of the regular solution heat treatment and natural aging described earlier in this paper.

Fig. 11 (left)—Fracturing characteristics of the aluminum alloy 24ST4 under cyclic straining at a strain of  $\epsilon_0 = \pm 0.12$  with and without intermediate reheat treatment, showing the permanent damage done by cyclic loading.

Fig. 12 (right)—Effect of repeated plastic tension on flow and fracture characteristics of the aluminum alloy 24ST4.

greater than the sum of two individual effects, Fig. 8.

3—Within the range of precompression and the number of cycles investigated, precompression accelerates the approach of fracture, Fig. 6.

4—Cyclic straining permanently damages the material, Figs. 10 and 11.

5—A pronounced yield jog appears after repeated tension cycles, and the flow and fracturing characteristics are slightly lowered, Fig. 12. This yield jog is not present in the virgin unstrained metal.

### Acknowledgments

The author gratefully acknowledges the interest of the Office of Naval Research in sponsoring this investigation and the permission of its publication. Very sincerely, the author expresses his appreciation to George Sachs and W. M. Baldwin, Jr. for their direction and encouragement and to K. H. Donaldson and L. J. Ebert for their management in conducting this investigation.

strain curves of the cyclically strained material are lower than the stress-strain curve of the virgin material.

In Fig. 11, the fracturing characteristics for specimens with and without inserted reheat treatment were plotted as functions of the number of cycles. This figure reveals that after a certain definite number of cycles, five in this case, the ductility of the cyclically strained material can no longer be restored to the value of the virgin material, regardless of the number of intermediate reheat treatments. However, at higher number of cycles, the amount restored by successive reheat treatment after each cycle is larger than that restored by a single reheat treatment before the final testing.

These all point to one fact, that the metal was damaged permanently by cyclic straining. This appeared to confirm the previous findings.<sup>10</sup>

**Stress-strain Curves for 24ST4 in Repeated Tension:** Fig. 12 shows the stress-strain curves for two specimens of the same material, one tested in tension continuously and the other subjected to 19 strain repetitions at a strain interval of approximately 0.01 and tested to fracture. Such repetitions of small plastic strains caused the following changes in the stress-strain behavior of this material: 1—Both the flow and the fracturing characteristics were slightly lowered. 2—A pronounced yield jog which the virgin material does not possess appeared after a number of repetitions.

Such slight reduction in both flow and fracturing characteristics is due apparently to the damages done by repeated loading.

### Conclusions

The experimental results lead to the following conclusions regarding this investigation:

1—Cyclic straining of re-solution heat treated 24ST4 creates two superimposed and counteracting effects, namely, strain hardening and deterioration. After small amounts of precompression, strain hardening prevails during the first few cycles, while after large precompression, deterioration prevails from the first cycle, Fig. 2.

2—When acting alone, either of the two factors, precompression or cyclic straining, causes a reduction in fracture stress of this material; on the other hand, when acting together, the combined effect is

# Effect of Alloying Elements on The Electrical Resistivity of Aluminum Alloys

by A. T. Robinson and J. E. Dorn

The electrical resistivities of aluminum alloys containing Cu, Ge, Zn, Ag, Cd, and Mg were found to increase linearly with the atomic percentage of the solute atoms. Application of Linde's rule to these data suggests that each aluminum atom contributes 2.5 electrons to the metallic bond.

**A**LTHOUGH aluminum invariably exhibits a valence of three in ionic solids, it does not follow necessarily that its valence in the metallic state is also three. As a matter of record, many properties suggest that the number of bonding electrons in metallic aluminum is less than three. For example, as shown in Fig. 1, the atomic radii<sup>1</sup> of the metallic elements in the solid state decrease with increasing atomic number at the beginning of any one period. The atomic radius of aluminum, however, is greater than that which would result from a regular decrease in atomic radius with increasing atomic number, suggesting that the number of bonding electrons in aluminum is somewhat less than three.

Correlated with the anomalously large atomic radius of aluminum is its abnormally low melting temperature. As the atomic numbers increase in any one period, the melting temperatures of the metallic elements increase.<sup>2</sup> As shown in Fig. 2, however, the melting temperature of aluminum (13) is only slightly greater than that of magnesium (12). Again the number of bonding electrons in metallic aluminum appears to be nearer two than the expected value of three.

In addition Ageev and Ageeva<sup>3</sup> calculated the electron density distribution in the aluminum lattice. A comparison of such electron density curves for various assumed valence states of aluminum

with experimentally determined curves suggests that the actual number of bonding electrons in metallic aluminum is between two and three. Hume-Rothery and Raynor<sup>4,5</sup> have suggested that the above-mentioned abnormalities are associated with the overlapping of the Brillouin zones of metallic aluminum when it is in the usual face-centered cubic structure.

The importance of the number of bonding electrons in metals has been extended recently into the field of mechanical properties. While formerly it was thought that the plastic properties of alpha solid solutions were primarily dependent upon the lattice strain induced in the solvent by the solute, it is now known that the difference in the number of bonding electrons of the solute and solvent also has its influence on the plastic properties.<sup>6,7</sup> In order to achieve a satisfactory correlation of the effect of alloying elements on the plastic properties of aluminum alloys,<sup>6,7</sup> however, it was necessary to assume that the number of bonding electrons contributed by aluminum was about two rather than the expected value of three. It appeared to be desirable, therefore, to seek other criteria for evaluating the number of bonding electrons contributed by aluminum to its alpha solid solutions, especially in view of the practical as well as the theoretical importance of the effect of valency on the plastic properties.

Norbury<sup>8</sup> was perhaps the first to illustrate that the increase in resistance of alpha solid solutions is associated with the differences in valence of the solute and solvent metals. In a series of illuminating investigations Linde<sup>9-11</sup> has shown that the electrical

Fig. 3—Agreement between calculated and observed resistance of various solid solution alloys of copper.

resistivity of alpha solid solutions in copper, silver, and gold closely obey the empirical relationship:

$$\Delta \rho = \{k_2 + k_1 (Z_\beta - Z_\alpha)^2\} A \quad [1]$$

where  $A$  is the atomic pct of the solute,  $Z_\alpha$  is the valence of the solvent,  $Z_\beta$  is the valence of the solute,  $\Delta \rho$  is the increase in resistivity per addition of  $A$ , and  $k_1$  and  $k_2$  are constants for any one period from which the solutes are selected.

The validity of the above relationship for alloys of copper is illustrated in Fig. 3 where the observed  $\Delta \rho$  is plotted as a function of the calculated  $\Delta \rho$  using the values of  $k_1$  and  $k_2$  given in Table I. In Figs. 4 and 5 are shown the validity of eq 1 for silver and for gold alloys using the data of Table I. The good agreement between  $\Delta \rho$  observed and  $\Delta \rho$  calculated reveals that eq 1 is quite accurate for the alloy systems which have been investigated.

It has been shown by Mott<sup>12, 13</sup> that the results of Linde as expressed by eq 1 have, in part, a simple theoretical explanation: The core of the solvent atom has a charge of  $Z_\alpha e$  whereas the core of the dissolved atom carries a charge of  $Z_\beta e$  which differs by  $(Z_\beta - Z_\alpha) e$  from that of the solvent. But since the intensity of the scattering of the conduction electrons is proportional to the square of the scattering charge, the change in resistivity should be proportional to  $(Z_\beta - Z_\alpha)^2$  when other factors are neglected.

In view of the above evidence, it should be possible, by application of eq 1 to alpha solid solutions of aluminum, to deduce the value of  $Z_\alpha$ , namely the charge on the core of the aluminum ions in metallic aluminum.

### Materials for Investigation

The alloys examined in this investigation were the same as those previously used for the determination of the effect of alloying elements on the plastic properties of aluminum.<sup>6, 7</sup> Their chemical analyses and their lattice constants are recorded in Table II. Each alloy was homogenized, cold rolled, and re-

crystallized to approximately uniform grain size preliminary to the determination of the resistivity.

### Experimental Procedure

Sheet-type specimens having nominal dimensions of 0.070 in. thick and 0.250 in. wide were used in this investigation. Their resistance was determined by means of a precision Kelvin double bridge ohmmeter, the specimen length between the potential leads of the Kelvin bridge being fixed at 2.750 in. The width and thickness of the specimens were measured at three points along their length by means of a vernier micrometer with a least count of 0.0001 in. The errors in the resistivity resulting from errors in gaging the specimen were determined

Fig. 7—Agreement between calculated and observed resistance of various solid solution alloys of aluminum.

to be insignificant. The sensitivity of the Kelvin bridge in the range which was used was slightly better than  $\pm 0.5$  pct. Total errors from these sources may have amounted to about  $\pm 0.5$  pct (or  $\pm 0.015$  microhm cm) of the calculated resistivity.

All resistance measurements were made at atmospheric temperature ( $22^\circ$  to  $26^\circ\text{C}$ ) and were corrected to  $24^\circ\text{C}$ . Since the temperature coefficient of resistivity of dilute alloys is known to be practically independent of composition,<sup>14</sup> a correction of 0.00429 microhm cm per  $^\circ\text{C}$  appropriate for 99.996 pct Al<sup>15</sup> was applied to each of the alloys.

### Experimental Results

The resistivities of the various alloys as a function of atomic percentage of the alloying element are given in Table III and plotted in Fig. 6. The usual linear increase of the resistivity of dilute solutions with atomic percentage of alloying element was obtained. The value for the electrical resistivity for pure aluminum was obtained by extrapolation of the data for each alloy series to zero concentration.

### Discussion and Conclusions

The atomic number and  $Z_\beta$  of each of the alloying elements used in this investigation are given in Table IV. Since elements Cu (29), Zn (30), and Ge (32) are in the same period of the periodic table, Norbury's rule as given by eq 1 was applied to the data

Table IV. Equation Constants Used for the Calculated Change in Resistance of the Aluminum Alloys

| Element | Atomic No. | $Z_\beta$ | $k_1$  | $k_2$  |
|---------|------------|-----------|--------|--------|
| Mg      | 12         | 2         | 1.832  | 0      |
| Al      | 13         | (2.5)     |        |        |
| Cu      | 29         | 1         | 0.2675 | 0.1731 |
| Zn      | 30         | 2         |        |        |
| Ge      | 32         | 4         |        |        |
| Ag      | 47         | 1         |        |        |
| Cd      | 48         | 2         | 0.2535 | 0.5446 |

obtained from these elements to determine  $k_1$ ,  $k_2$ , and  $Z_\alpha$ . The value of  $Z_\alpha$  thus obtained was 2.50 and indicates again that the aluminum ion in the metallic state has a charge of about  $-2.5$  electrons.

Using the values of  $k_1$  and  $k_2$  given in Table IV and assuming that the ionic charge of aluminum is  $-2.50$  electrons, the correlation between  $\Delta\rho$  calculated and  $\Delta\rho$  observed shown in Fig. 7 was obtained.

Thus, the effect of alloying additions of Cu, Zn, Ge, Ag, Cd, and Mg to aluminum on its electrical resistivity has been determined; and applying the Norbury rule to the resistivity of aluminum alloys suggests that the apparent valence of aluminum is approximately 2.5.

### Acknowledgments

This investigation was conducted under the sponsorship of the Office of Naval Research. The authors wish to express their appreciation to the O.N.R. for its continued interest throughout the course of these studies. They also wish to thank T. E. Tietz and A. Goldberg for their interest and criticism during the experimental phase, and Mrs. G. Pelatowski for her careful preparation of the figures. They are also very grateful to M. Nathans for his advice and suggestions which greatly facilitated this investigation.

# Growth of Molybdenum Single Crystals

by N. K. Chen, R. Maddin, and R. B. Pond

A METHOD has been described by Andrade<sup>1</sup> for obtaining very rapid grain growth so that single crystals of high melting point metals could be made with comparative ease. The furnace construction was essentially a very thin wire through which was passed an electrical current so that "a high uniform temperature" was maintained. The wire was surrounded by a fused quartz tube from which the air had been evacuated. Andrade applied this method to the growth of single-crystal wires of alpha iron, and Tsien and Chow<sup>2</sup> prepared single crystals of molybdenum 0.25 mm diam in this way.

In the present report a method is described in which the basic idea of the Andrade furnace is utilized. However, modifications are employed so that large single crystals of molybdenum or of any refractory metals can be grown.

## Furnace

The modified Andrade furnace is shown in Fig. 1, and the detailed drawing of its construction can be seen in Fig. 2. The furnace proper consists of a 2½-in. diam fused silica tube, 20 in. long, which is evacuated continuously at the bottom. Two water-cooled copper electrodes hold the specimen by means of collets held in place in the electrodes by set screws. These electrodes serve also to transmit power to the specimen. The lower electrodes can be clamped to the stand, while the upper electrode is fastened in place to the bellows which in turn is further connected to one side of the lever arm, flexibly supported at the top. After the specimen is mounted and the vacuum is secured, the lever arm is adjusted by means of the counter weight so

Discussion on this paper, TP 3048E, may be sent (2 copies) to AIME by Aug. 1, 1951. Manuscript, Oct. 19, 1950; revision, March 2, 1951. St. Louis Meeting, February 1951.

that the bellows is at its relaxed position. This insures that the total weight of the specimen, the upper electrode, and the downpull of the vacuum are balanced by the horizontal beam. Any expansion of the specimen on heating should proceed freely, if other frictional forces could be neglected. During the time of heating the specimen, the beam is maintained in a horizontal position by turning the nut at the top, the rotation of the electrode is prevented by a key fitted into a groove. This arrangement proved very desirable in that buckling of the specimen during the high temperature treatment was avoided.

The power is supplied by a motor generator set with a capacity of 550 amp at a maximum of 24 v. Results indicated that for a  $\frac{1}{8}$ -in. diam, 6-in. long molybdenum rod, a current in the vicinity of 210 amp at 2.5 v could heat the specimen up to an average temperature of 2000°C.

The subsidiary external furnace is wound with nichrome so that the electric heating zone is a cylindrical band  $\frac{1}{2}$  in. wide. It can be raised or lowered by the attached motor whose speed may be varied by means of an electronic controller from 0.5 to 15 in. per hr.

### Temperature Measurement

The average temperature of the specimen can be measured from the change in its resistance with temperature. As may be seen in Fig. 3, a linear relationship of specific resistance of molybdenum with temperature exists up to its melting point.<sup>8</sup> Thus, when the total current is measured, together with the voltage drop across the specimen, the corresponding resistance can be used to indicate the average temperature. Fig. 4 shows the E-I characteristic curve, measured for three specimens of  $\frac{1}{8}$ -in. Fansteel molybdenum rod, 6 in. long. The current through the specimen is adjusted by controlling the field resistance of the generator with electric stoves and a rheostat. After the current and voltage have been stabilized corresponding to a particular average temperature of the specimen, this equilibrium condition can be maintained for a long time.

### Experimental Results

The original material used was  $\frac{1}{8}$  and  $\frac{1}{4}$ -in. diam, 6-in. long Fansteel molybdenum with a grain size far smaller than could be denoted by any ASTM designation, as shown in Fig. 5. Its longitudinal section exhibited long fibrous grains, Fig. 6. The first specimen, M-1, was heated to an average temperature of about 2000°C for 90 min. Since no arrangement was designed to account for the ex-

pansion of the specimen in this first run, the specimen buckled and broke into three pieces, with a brittle fracture, when disassembled from the furnace. Nevertheless, back-reflection Laue photographs exhibited a large amount of grain growth in this short period of heat treatment, as shown in Fig. 7. Three other specimens, M-2, M-3, and M-4, were heated in the furnace according to the time-temperature curve shown in Fig. 8. These attempts still resulted in buckling of the specimens which was probably due to the force necessary to overcome friction in the system, namely, friction of the electrodes against the surface of their receptacles. This was overcome by minimizing the friction.

From Fig. 7 it may be concluded that all three specimens resulted in single crystals of certain lengths. M-3 revealed three grains thermally etched, each extending through the whole crystal with lengths of  $\frac{3}{4}$  to  $1\frac{1}{4}$  in. The surface of the specimen was bright, the grain boundaries being clearly revealed when the specimen was removed from the furnace. All specimens were electrolytically polished using an electrolyte of 300 cc methyl alcohol, 60 cc  $H_2SO_4$ , 130 cc HCl, and a current density of 4 amp per sq in. After etching with NaOH-KFe<sub>3</sub>(CN)<sub>6</sub> solution, the grain boundaries of the large grains, as well as some surface grains distributed as islands in the large grains, could be observed. Thus M-2 showed a grain about  $\frac{2}{5}$  in. in length which confirmed the X-ray observations shown in Fig. 7, although the lower middle photographs, M-2, exhibited three grains and M-4 two large grains about  $1\frac{1}{4}$  in. long extending through the whole specimen. The polycrystalline material shown adjacent to the large single grain in Fig. 9 had an average ASTM grain size of No. 3. With the  $\frac{1}{4}$ -in. material it was found necessary to recrystallize the as-received molybdenum rod and to extend the specimen 1 to 2 pct in order to provide a strain. Following this procedure, a total of 7 hr was required to produce single crystals approximately  $1\frac{1}{2}$  in. long.

While the specimen was maintained at high temperature, considerable evaporation occurred and a film of metal formed on the inside wall of the silica tube. The zone of this deposition extended through the middle 6 in. of the tube.

### Discussion

The modified Andrade equipment has overcome the limitations of the original Andrade method in

Fig. 3—Effect of temperature on electrical resistance of molybdenum.

Fig. 4—E-I characteristic curve for  $\frac{1}{8}$ -in. Fansteel molybdenum rod 6 in. long.

Fig. 5 (left)—Grain size of as-received Fansteel molybdenum  $\frac{1}{8}$ -in. rod cross-section. Etchant  $\text{NaOH}:\text{K}_3\text{Fe}(\text{CN})_6$ . X100.

that only very fine wire could be used with his equipment as a starting material. With the present arrangement, material of rather large size, i.e.,  $\frac{1}{2}$ -in. rod, can be converted into single crystalline form.

The very rapid grain growth observed in these experiments over the relatively short time employed is of great interest. Since both ends of the specimen are at room temperature, about  $35^\circ\text{C}$ , where the center section is maintained at a temperature higher than  $2000^\circ\text{C}$ , a very sharp temperature gradient exists in the specimen. It is not known whether the sharp gradient or the high temperature is responsible for the rapid grain growth, nor is it possible at the present time and with the present equipment to measure or calculate accurately the temperature gradient along the rod. A simple uniform variation of temperature was assumed and the average temperature resulting

from this distribution was calculated. With this assumed temperature gradient the total average resistance assuming different lengths of rod was determined. By this method the temperature of the rod was calculated as shown in Fig. 8. There was little doubt that the temperature at the center of the rod exceeded  $2000^\circ\text{C}$  when the average temperature for a length of 4 in. was measured as  $2000^\circ\text{C}$ .

It is interesting to note that Tsien and Chow, in their original experiments, used the subsidiary furnace "to establish a temperature gradient." Without the use of the subsidiary furnace, single crystals never exceeded 2 mm in length. However, it is probable that the external furnace has little or no effect on the final outcome of the experiments since the sharpest temperature gradient exists in the specimen itself as a result of the water-cooled ends.

Fig. 7—Back-reflection Laue photographs. Specimens M-2, M-3, and M-4 were treated as shown in Fig. 8. Original material, upper left. Specimen M-1, 40 min at  $2000^\circ\text{C}$ , lower left. Specimen M-2, upper center. Specimen M-2, lower center. Specimen M-3, upper right. Specimen M-4, lower right.

Fig. 8 (left)—Time-temperature curve showing heating process of specimens M-2, M-3, and M-4.

Fig. 9 (right)—Interface between single crystal and fine grained molybdenum rod. Electrolytically polished. Etchant,  $\text{NaOH}:\text{K}_3\text{Fe}(\text{CN})_6$ . X150.

No observable difference in the results could be noted when the external furnace was used in the present case.

# Relationships Between Germanium and Cadmium In the Electrolysis of Zinc Sulphate Solutions

by S. T. Ross and J. L. Bray

The paper provides electrometallurgical data on the problem of germanium removal from zinc sulphate solutions. Germanium traces have caused much concern to the zinc refiner. Confirmatory evidence of interaction between germanium and cadmium is presented. Statistical analysis of data expands its significance and enhances its value. Further research is outlined.

THE literature contains many references to the effects of trace amounts of germanium in the production of electrolytic zinc. One of the authors had experience with this troublesome element as early as 1917 at Trail, B. C. In 1929, Tainton and Clayton<sup>1</sup> reported that concentrations of as little as one part per million of germanium were sufficient to cause serious losses in current efficiency. Liddell<sup>2</sup> reported that trace amounts of germanium cause marked lowering of the hydrogen overvoltage of electrolytic zinc cells, so that commercial production was impaired. Bray<sup>3</sup> recorded the history of germanium in relation to electrolytic zinc production, noting that concentrations below 10 ppm have been found to yield low current efficiencies and copious hydrogen evolution. Koehler<sup>4</sup> stated that germanium "when present to the extent of a small fraction of one part per million per liter, causes serious evolution of hydrogen with a corresponding reduction in current efficiency."

Recently, however, S. W. Ross<sup>5</sup> reported, from Risdon, Tasmania, that "in the course of leaching ... dissolved traces of germanium ... if not removed almost completely ... increase the reversion of cadmium during the filtration of the copper-cadmium precipitate and reduce the current efficiency during subsequent analysis." The copper-cadmium precipitate referred to is the residue from the zinc-dusting purification of zinc sulphate leach solutions.

In the face of such conflicting testimony and with the increasing industrial importance of pure germanium and zinc it was decided to investigate the relationship between cadmium and germanium. Furthermore, other work by the authors showed certain discrepancies to exist in the theories of Tainton, et al. In the laboratory, without marked efficiency decreases, the authors have deposited zinc successfully from solutions containing as high as 1 g per liter of germanium. This could be done only when there was no cadmium present.

Preliminary investigations of the suspected rela-

tionships were carried out by means of emission spectrographic analysis using a beryllium internal standard. Several solutions containing 100 g per liter of zinc, as zinc sulphate, and 1 g per liter of cadmium, as cadmium chloride, were prepared. These concentrations were on the order of those obtained during a commercial low-acid leaching process. Varying concentrations of germanium were added to these solutions so that the range of 0.0000 to 0.5000 g per liter of germanium was covered. A 250 ml sample of each solution was agitated with 2.5 g of zinc dust for 30 min, filtered, and the filtrates were examined spectroscopically. Qualitative evidences of cadmium traces were found in those filtrates which originally contained above 10 ppm of germanium. Reliability of the analytical method did not permit quantitative investigations since cad-

\* Cd and Ge concentrations shown are those existing before zinc-dust purification.

mium determination in the concentrations present in zinc-dusted solutions lacks sufficient sensitivity for reproducible results.

As a consequence of the inability of the investigators to obtain acceptable results through direct quantitative analysis, an indirect approach was devised. This indirect method involved a study of the current efficiency, in a model zinc cell, as a function of the concentrations of cadmium and germanium. Variables such as cell temperature, voltage, current density, anode spacing, relative electrode area, degree of agitation, cathode preparation technique, time, acid concentration, and solution volume were held constant.

Fig. 1 shows the cell used. The current was fur-

Fig. 1—Model zinc cell.

nished by a 10 v storage battery bank. The anodes were high purity sheet lead, approximately 2x4x $\frac{1}{4}$  in. The cathodes of 2S aluminum alloy sheets were 0.060 in. thick,  $\frac{1}{2}$  hard, cut into 1-in. squares. The anodes were separated by a wooden spacer which had been dipped in paraffin to prevent possible side reactions from occurring. The current was kept constant at 0.425 amp for each run—a current density of approximately 30 amp per sq ft. Each run was accomplished at room temperature without agitation. Each solution contained 100 g of zinc per liter, as zinc sulphate, and each run was made with a 250 ml volume of solution. Each cathode was degreased with trichloroethylene before electrolysis. Each solution was treated with 2.5 g of zinc dust for 30 min, with agitation, and filtered before electrolysis. Measurements were taken of the weight of each

cathode before and after electrodeposition, and the weight of zinc deposited was obtained as a difference. The current efficiency of each run was calculated according to Faraday's law.

### Experimental Results

Table I lists the analyses, before zinc dusting, and current efficiencies obtained from solutions varying from 0.0000 to 0.0100 g per liter of germanium at the 0.0000 and 1.5000 g per liter concentration levels of cadmium. The time of each run was 30 min. Fig. 2 shows that the current efficiency, when plotted against the germanium concentration, tends to drop off rather sharply with increasing germanium content at the 1.5000 g per liter level of cadmium concentration, while remaining relatively constant at the 0.0000 g per liter cadmium concentration level.

**Expanded Data:** For evidence of the interaction between cadmium and germanium, the data were expanded and an analysis of variance was performed. For cadmium concentrations of 0.0000 to 2.5000 g per liter in combination with germanium contents of 0.0000 to 0.1000 g per liter, three plating runs were made for each zinc sulphate solution. The runs were of 60, 30, and 15 min duration to obtain replication of the statistics, as well as to investigate the variable of plating time. All other factors were

|                       | 15            | 94.926          | 94.617 | 87.980 | 87.517 | 85.125 |

\* These statistics were obtained from conversion of the weights of deposited zinc through the application of Faraday's law. The statistics are current efficiencies in percent. Percent current efficiencies =  $\text{Wt Zn} \times 1157.636 \div \text{Cadmium and germanium concentrations shown are those existing before zinc-dust purification.}$

Time in min

held constant, as described before. Table II shows the tabulated results of 75 runs made in random order. Randomization was achieved by assigning numbers 1 to 75 to each run, and performing each run in the order in which its number appeared in a table of random numbers as prepared by Fisher and Yates.<sup>6</sup> Randomness was desired to remove as much of the cumulative effects of error as possible (e.g., possible effects due to a build-up of anode reaction products in the solutions, etc.).

**Analysis of Variance:** An analysis of variance was performed on the data of Table II using the method of Freeman.<sup>7</sup> Essentially, the method consisted of obtaining the variance due to each factor, or combination of factors, and comparing it for significance with the variance due to error.

The significance of the interaction of cadmium and germanium concentrations was thus established. By indirect means, it substantiated the fact, only

Fig. 2—Current efficiencies at 0.0000 and 1.5000 g per liter Cd levels.

hinted at by the spectrograph, that the chemical interaction of germanium and cadmium is of significance in consideration of electrolytic zinc cell problems. Analysis of variance showed that the interaction of germanium and cadmium was of such statistical importance that it must be regarded as a factor in the variation of cell current efficiencies due to other than random causes.

**Significance of Difference:** To obtain further evidence of the relationship between germanium and cadmium, the solutions on the 0.0000 and the 1.0000 g per liter levels of cadmium concentrations were investigated in a somewhat different manner. A test for the significance of the difference of the means of these two groups of data was made. The methods of "Student"<sup>8</sup> and Fisher<sup>9</sup> were followed.

Such calculations indicated that a statistically significant difference existed between mean values of the data. The primary assignable cause of that difference was variation of the cadmium concentration. Such random errors as may have been introduced by slight fluctuations of other variables were minimized by the method of calculation.

### Summary and Conclusions

The significance of difference and analysis of variance tests as performed on the above data substantiate the claim that definite interaction exists in the zinc cell between cadmium and germanium concentrations. Germanium alone, within normal operating limits, does not cause large current efficiency losses. Rather, this research indicates that the adverse effects of germanium are notably enhanced by the presence of cadmium, and that the presence of germanium in leach solutions of the commercial zinc sulphate type precludes the complete removal of cadmium from them. This leads to further ques-

tions, as yet unsettled. What, if any, are the effects of the interactions of other impurities such as arsenic, antimony, bismuth, and lead, in the minute quantities found present after purification by present methods? How is the cell overvoltage affected by these interactions? What is the physical-chemical answer to the existence of such interactions? These are now being investigated in this laboratory.

While the answers to these questions are of academic interest, the commercial picture remains the same. Regardless of the nature of the interactions, germanium and cadmium must be removed in sufficient quantity before efficient electrowinning of germanium-tainted ores can be accomplished. It does not matter to the zinc producer whether germanium causes efficiency losses directly, or whether germanium and cadmium cause efficiency losses. In either event, the difficulty is there and a remedy must be found.

### Technical Note

## Deformation Texture of Cold-Drawn Copper Wire

by Walter R. Hibbard, Jr.

BACKOFEN<sup>1</sup> reported recently that "the deformation texture of cold-drawn OFHC copper wire, after a reduction in area of 97.3 pct, may still be described as a composite of [111] and [100] directions aligned parallel to the wire axis." In the introduction, he indicated that this was in contrast to the work of Hibbard,<sup>2</sup> who reported a single [111] texture after a reduction of 96.4 pct. Unfortunately Backofen stated that this was a reduction in area when actually it was a reduction in diameter, as is clearly stated in the reference. Moreover, the results of Backofen are in complete agreement with the results of Hibbard. Backofen's 97.3 pct reduction in area is an 83.3 pct reduction in diameter, after which he found a double [111] and [100] texture with the former predominating. Similarly, Hibbard,<sup>2</sup> after an 86 pct reduction in diameter found a double [111] and [100] texture with the former predom-

inating. Hibbard, however, when he drew the wire further to 96.4 pct reduction in diameter, found primarily a single [111] texture as illustrated by Fig. 2 of ref. 3. Here also, Hibbard<sup>3</sup> reported evidences of the [100] recrystallization texture found by Backofen. It might also be pointed out that Backofen not only drew his wire 97.3 pct reduction in area but also etched them over 99 pct reduction in area from 0.125 to 0.01 in. diam. Hibbard's wires were drawn directly to size.

In summary, the deformation texture of cold-drawn copper wire still may be described as primarily a single [111] texture after a sufficient amount of drawing, such as 96.4 pct reduction in diameter.<sup>2,3</sup>

# Electric Furnace Melting Of Copper at Baltimore

by Peter R. Drummond

THE final casting of refined copper has been restricted for generations by the following sequence of operations: Filling the reverberatory furnace, melting, skimming, blowing or flapping, and poling. The hoped-for 24 hr cycle, producing 300 tons or more, has been taken up largely with the necessary but time-consuming tasks of cleaning the bath, sulphur elimination, and in turn removal of excess oxygen to produce tough-pitch copper. Incidental to comparatively slow melting under combustion gases, copper oxides react with the furnace lining, and the slag so-formed must be completely recycled.

The three-phase arc furnace has eliminated some of the cycle stages, and telescoped the remainder into a continuous operation. Electrical energy, supplied to graphite electrodes enclosed in high grade refractories, rapidly melts copper cathodes and sustains a stream of metal, containing approximately 0.01 pct oxygen, without contamination from fuel.

The arc was struck on the first large electric furnace for melting copper in the United States on April 13, 1949. The earliest use of this type of furnace was at Copper Cliff, Ont., in 1936, and an admirable description of their installation has been published.<sup>1</sup> Copper, melted in the Baltimore furnace, is used to cast billets, and the installation differs somewhat from the Canadian, as will be described.

The arc furnace is a heavy-duty, three-phase furnace, holding 50 tons, the general outline of which appears on Fig. 1. The steel shell is 15 ft ID with a bottom radius of 14 ft 2 in. The roof, separate and distinct from the body, consists of a 15-ft water-cooled, cast-steel ring of the same outside diameter as the furnace. The center line of the furnace lies 9 ft 6 in. from that of the trunnions, permitting a 5° backward tilt for skimming, and a 40° maximum nose tilt forward for complete draining. Normally, the furnace overflows by displacement, and the use of the forward tilt arrangement is restricted to covering charging delays.

The charging slot, 3 ft 8 in. x 5 in., lies on the north center line, the tap hole on the south, and the 30x30 in. skim door 45° to the west of the slot.

The original 20-in. graphite electrodes were replaced with 14 in. in December 1949. Three conventional direct current winch drives, governed by electrical controls, position each electrode which has individual mast supports and counterweights. An independent circulation supplies cooling water for the

electrode glands, the roof ring, charge slot, and the skim door frame.

## Arc Furnace Refractories

**Hearth:** Fused-in monolithic bottoms had been used in copper arc furnaces, installed prior to April 1949. These consisted of thin layers of periclase, successively fused in place over preliminary brick courses. Heat was obtained from the arc, using a T-like arrangement of broken electrodes resting directly on the periclase to be fused. The operation, taking weeks to perform, was very expensive. The chemically-bonded magnesite-brick bottom, installed at Baltimore, was the first of its kind and a radical departure from previous practice.

It consists of a 1 to 6-in. layer of castable refractory laid on the steel shell, modifying it to a 12 ft 2 in. bottom radius. Two courses of 9x2½-in. fireclay straights and keys follow.

The third course is made of 9-in. magnesite blocks of special shape to form circles of an inverted arch. It was started by a four piece keystone with skewbacks forming the outer course. The fourth course also started on a central keystone, or button, of four 90° segments, 12 in. diam x 13½ in. deep, and continued with 13½-in. blocks. Skewbacks at the shell completed the course to produce a horizontal surface for the side walls with a single course of No. 2 arch fireclay against the steel.

Dry chrome-magnesite cement was brushed over each course after laying, and a 1-in. expansion space between the brick and the shell was filled with the same mixture. The total bottom thickness, excluding the castable material, was 5 in. of clay plus 22½ in. of chemically-bonded magnesite.

**Tap Hole:** A 5-in. OD and 3-in. ID silicon-carbide tube constitutes the tap hole and is set tangential to the upper course of the furnace bottom. Molten metal fills the tube when the furnace is level and filled to capacity.

**Side Walls:** The lining, against the shell, consists of a 9x4½x3 in. soldier course of fireclay, using straights and No. 1 arches to turn the circles. A second soldier course of 9x4½x2½-in. fireclay was laid in a somewhat similar fashion.

Three courses of 13½x6x3 in. and 9x6x3 in. of final magnesite, laid flat, completed the lining, using Nos. 1 and 2 keys to turn the circles. Cardboard spacers were placed between every two bricks in horizontal courses, and a thin coat of chrome-magnesite cement filled the joints between the firebrick and magnesite. A sprung-arch spanned the skim door with jambs of suitable magnesite shapes.

**Charge Slot:** The slot is 3 ft 8 in. wide x 5 in. high. A silicon-carbide sill of special shapes has a 30° slope to allow cathodes to slide easily into the bath. The original arch was flat, and composed of Nos. 1 and 2 wedge magnesite with a 6-ft radius. It projected 5 in. over the sill, and, being a flat arch, gave an 18 15/16-in. opening between the inner edge and the metal line. The whole assembly was later raised 9 in., and the flat arch replaced with an arch, the lower edge of which maintained the 5-in. width from the outer to inner edges as shown in Fig. 2. A water-cooled, cast-copper jacket protects the steel shell behind the slot.

PETER R. DRUMMOND, Member AIME, is Chief Metallurgist, Baltimore Plant, American Smelting and Refining Co., Baltimore.

Discussion on this paper, TP 3064D, may be sent, 2 copies, to AIME by Aug. 1, 1951. Manuscript, Dec. 22, 1951. St. Louis Meeting, February 1951.

<sup>1</sup> Trans. Canadian Inst. of Min. and Met. (1946) 49, pp 199-222.

**Roof:** A single course of fire-clay skewbacks of special shape encircle the water-cooled ring. The remainder of the roof embodies standard sprung-arch construction, using bonded 9-in. magnesite of 3 and 2½-in. arches, straights, and wedges with special shapes as required to turn the circles, and with cardboard expansion joints between every fifth brick. The three electrode openings and a vent are turned respectively with 13½x4½x2½ in. and 9x4½x2½ in. magnesite arches.

**Launder:** A 30-ft steel-framed launder, a cross-section of which appears on Fig. 1, connects the arc furnace with a low frequency induction furnace. Three 9x4½x2½-in. silica insulating brick line the bottom with a course along each side, laid flat, leaving 2-in. side spaces which are both filled with loose silica insulation. Suitable fireclay shapes support the central silicon-carbide V channel, formed with one 1½-in. split laid flat and two 9-in. splits at a 60° angle, giving a roughly equilateral channel 9 in. deep x 10 in. wide at the top. Joints are filled with silicon-carbide cement. Courses of clay brick, two of 12x12x2 in. and one of 12x6x3 in. cover the channel.

**Induction Furnace:** This holds about 5 tons, appears in outline on Fig. 3, and serves merely as a reservoir between the arc and the casting ladles. Power control will be described under electrical equipment. Metal enters the unit from the launder through a 6 in. OD x 4 in. ID silicon-carbide tube inserted through one furnace trunnion. The furnace pours into casting ladles through a similar tube set at an angle to allow complete drainage without going beyond 90° from the vertical.

The unit comprises two sections: A body and separate induction slot. A steel casing constitutes the vertical shell and is lined with one soldier course of 4½-in. insulating firebrick and a course of chemically bonded 9-in. magnesite keys. The steel roof cover is filled with a castable refractory and clamps to the shell. A rammed 9-in. Mullite bottom is connected with the slot proper through an opening 24½x6 in. tapering to 21½x3 in.

The induction unit bolts to the foregoing. Each unit is rammed with Mullite, containing 6 pct moisture. This requires considerable technique, and once started, is carried to completion in 10 to 12 hr without interruption. After ramming, the units are heated electrically and dried before being put into service.

Two thermocouples, lying against the metal core bushing of the primary induction unit, connect with a recording potentiometer, by means of which core failure can be predicted. An independent 750 psi hydraulic system is used to tilt the induction unit for pouring about one ton of metal in 34 sec.

**Charging Machine:** Cathodes, to be charged to the arc furnace, are piled 20 high on pallets and travel by gravity on rollers to a shear, where the loops are removed. The cathode is then pushed into the charging machine magazine, which constitutes a novel feature of the installation.

Fig. 1—Section through center line of arc furnace showing refractory lining.

The storage magazine consists of two endless parallel chain conveyors, mounted on a frame at 60° from the horizontal, to hold the cathodes. The chains carry a series of parallel plates, which form slots, and as a cathode comes to rest on one of them, its weight actuates a switch, energizing the drive motor to move the magazine one position upwards and so insure the presence of one sheet at a time in each slot. Fully loaded, the magazine holds approximately a 30-min supply for the furnace, and one man per shift can handle all charging into the furnace.

An elevating mechanism is interposed between the storage magazine and the furnace charging slot. This descends on tracks until two hooked members intercept the first closed pair of magazine gates, holding the topmost cathode. The members energize suitable relays, stop the elevator, open the gates allowing the cathode to slide into the elevator, and, by automatically reversing the drive, return the carriage to the charging position.

A timer, which can be set to charge cathodes at any desired rate, controls two more or less simultaneous actions. It opens the furnace door and at the same time actuates a pusher which thrusts the cathodes through the slot. The ram withdraws, the furnace door closes automatically, and the elevator drops to continue the cycle.

**Electrical Equipment:** The local electric utility company supplies power over a three-phase 60-cycle, 13.8 kv overhead line supported on wooden poles and pin insulators. The line terminates 100 ft from the furnace substation, where it changes to a three-conductor leaded cable laid underground in fiber ducts.

The two-story furnace substation is of fireproof construction in conformity with the local building code. The first floor contains a six-section, high-voltage, metal-clad oil circuit breaker switch gear, station control battery, a necessary charging motor generator set, a furnace-rotating regulator set, and one six-circuit three-phase 440 v free-standing, metal-clad air circuit breaker switch gear serving arc furnace equipment. The second floor carries: one 250 kva—13.8 kv primary to 480 v secondary self-cooled, oil-insulated, single-phase, 60-cycle transformer for the low frequency induction furnace; one 6000 kva—13.8 kv primary to 85 to 225 v secondary,

Fig. 2—Present charging slot.

water-cooled, oil-insulated, three-phase, 60-cycle transformer with tap changer for the arc furnace; and one 750 kva—13.8 kv primary to 480 v secondary, self-cooled, oil-insulated, three-phase, 60-cycle transformer serving arc furnace equipment.

The transformers stand directly above their respective oil circuit breakers and are wired with single conductor, varnished-cambric, flameproof cable through fiber ducts enclosed in steel. The floor is constructed to form a liquid-tight basin to take care of a possible transformer tank failure.

The arc furnace transformer is in line with the vertical center line of the furnace and at sufficient height to minimize the heavy rigid secondary copper buswork and to provide clearance and free movement for the flexible cable loops between the bus and the electrode mast arms. The bare copper cables, connecting the bus and mast arms, consist of twenty 1,500,000 circular mil and twelve 1,750,000 circular mil cables per phase.

The arc transformer secondary is connected in Y and the primary in delta. The primary taps permit the following secondary line to line volts: 225, 208, 190, 173, 156, 147, 130, 120, 110, 100, 90, and 85. At the present time the furnace is operated on 190, 173, 156, and 130 v.

The furnace operating control panel is flush with the station wall, and the back is readily accessible for inside repairs through a door adjacent to the panel. The main initiating control for the charging machine is on the same panel, in addition to conventional instrumentation and arc furnace controls.

A 12-lantern semaphore occupies a position to one side of the operating panel, and a solenoid-operated air whistle attracts the operator's attention to: 1—Tripping of any of the substation high voltage breakers, 2—power failure on the 250 v dc supply exciting either the rotating regulator or the electrode winch motor, 3—overheating of the arc furnace transformer, 4—low transformer oil levels, 5—power failure on the induction unit, 6—cooling fan failure, 7—high arc furnace side wall temperatures, 8—charging machine failure, and 9—failure of station control battery charging equipment.

A silicon-carbide target tube is set flush with inner side wall lining of the arc furnace, and a radiation pyrometer, sighted on this, indicates side wall temperatures which are recorded continuously. An adjustable contact-making device connects the recorder with the semaphore.

The low voltage, free-standing, metal-clad switch gear and controller for the induction furnace unit stands adjacent to the casting platform. This houses the main air circuit breaker, tapped autotransformer, power-factor correction capacitors, manual pre-setting tap switches, and magnetic solenoid tap changing contactor. Indicating power-factor and kilowatt meters, furnace molten metal electronic temperature recorder and controller, and furnace inductor core sleeve electronic temperature recorders are set flush on front of the switch gear cubicle.

The inductor core is rated 100 kva, the auto-transformer at 125 kva, 460 v, and is high tapped at 460, 440, and 380, with low at 250, 200, and 150. The manual selector switch preselects any one of both the high and low tap voltages. Then, the two solenoid-operated magnetic switches automatically control the furnace power input from the pre-selected taps. These, in turn, are dictated by electronic control received from the radiation pyrometer sighted on a silicon-carbide tube submerged in the metal bath.

The furnace currently operates on the 380 v high tap and 250 low, providing a power input of 65 and 30 kw respectively at 85 pct line power factor.

*Seasoning:* The brick hearth embodied a radical departure from previous practice, so, details of pre-heating and some history of the lining follow as contributory to the success of the furnace bottom.

Drying of the brick bottom began at 1:40 p. m., April 4, 1949, and the furnace was slowly brought to 2070°F by 7:20 a. m., April 11 by the use of an oil burner. The rise in temperature was controlled carefully by means of a thermocouple lying on the hearth with lead wires through the tap hole. The average rise was 11.8°F per hr.

After removing the burner, five tons of starting sheet scrap were charged. Six tons of ingots were then thrown on the cushion of scrap and the burner replaced. By 4 p. m. of the same day the charge was flat and the wall temperature 1900°F. The furnace was rocked back and forth intermittently until 11:10 p. m. to allow the molten metal to fill the interstices between the brick, the burner was then removed, and the furnace drained.

By 12:45 p. m. a second addition of 8.2 tons of starting sheets was charged. This was molten by 4:30 a. m., April 12, and ingots were then charged. By 9:15 a. m., 30.8 tons of ingots had been added. The charge was flat by 10:10 a. m., and the wall temperature 2020°F. Firing continued until 7:45 a. m. of the following day to raise the metal temperature. The burner was removed, and the electrodes lowered into the furnace. The side walls had reached 2120°F, and the arc was struck at 8:25 a. m. Power was used intermittently to familiarize the operators with the controls until 4:32 p. m. when cathode charging started.

The distinctive difference between burned-in bottom practice and the foregoing is that in burning in a bottom the arc is struck over a bare hearth whereas the brick bottom has never been subjected to direct radiation and possible local overheating. The wash-out charge made a copper-bonded monolith of the brick by allowing the metal to penetrate to a depth where it naturally froze, and the preliminary melt of 40 tons under oil assured that the bottom did not attain a temperature above that of the bath.

On Aug. 6, 1949, after 120 days of operation, the furnace was drained and cooled slowly, primarily

to replace the charging slot, the reason for which is explained below. Examination of the bottom at that time showed a slight build up of approximately  $\frac{1}{2}$  in. except for the central starting button of the upper course which had spalled to a depth of 2 in.

No repairs were made to the bottom, but a segment of the side wall, amounting to about one quarter of the circumference and including the skim door and charging slot, was replaced. A hot-metal charging slot was cut in the wall near the tap hole, and since then molten copper from the reverberatories has been used for the initial filling.

**Charging Slot:** The charging slot has been the cause of considerable delay. Copper accretions collect gradually in the opening, causing cathodes to jam. These accretions may be back splash from cathodes, metal surges caused by the arc, or a combination of both.

Details of the slot were presented in the general description, but it is noted again that the height of the opening increases from 5 in. at the shell to 18 15/16 in. at the inner face. This aperture facing the electrodes appears to act as an open trap for splash, and a change was made early in June 1950 to improve this condition.

This improvement consisted of raising the charging slot 9 in. above its previous location. In addition to raising the slot, a silicon-carbide arch, which maintains the 5 in. height throughout, was installed. The new slot appears on Fig. 2 and, as can be seen, it overhangs and partially protects the lower sill from splash. The charging delays for jammed cathodes and slot cleaning have been reduced greatly.

The silicon-carbide sill still presents a problem as this material quickly oxidizes. There is apparently a reaction between the oxides of copper and the carbide, as boiling can be seen around the lower edge of the sill. A periclase brick sill will be tried at the next repair, but the furnace has operated successfully for months with little or no sill brick.

**Quality Control of Metal:** Delivery of good quality cathodes leaves control of arc furnace metal dependent on the three elements: Oxygen, sulphur, and iron. This resembles reverberatory practice, but manipulation differs. The three elements are dealt with in order.

The arc furnace is vented by a 9-in. diam circular opening, six courses in from the side of the roof. An open bonnet, a few inches above the aperture is connected to a 5500 cfm fan. Regulation of air entering the furnace is obtained by changing the size of the roof vent with a movable brick cover.

The operators take two samples each hour, one from the arc furnace tap hole and one from the induction unit. The physical laboratory determines oxygen optically on cubes made from the samples and reports the results to the furnace foreman. Oxygen ranges from a trace to 0.02 pct with an ideal of 0.01 pct. The furnacemen regulate the roof vent in accordance with the analyses.

Sulphur could originate from the electrodes, the furnace lining, or the cathodes. Sampling and analysis of each electrode shipment has shown no sulphur. Chemically-bonded magnesite brick contains sulphates. As a result excess sulphur shows up for a time after a repair, but drops rapidly in a few hours; and the sulphur content soon becomes normal.

Sulphur control, therefore, centers on maximum removal of the sulphates and sulphuric acid from

Fig. 3—Induction holding furnace for copper, 5-ton capacity, 100 kva.

the cathodes as they come from the tanks. This, obviously, is a washing problem, and sulphur removal has evolved along the following lines. The tank house has been equipped with twin dip tanks of sufficient size to take a whole lift of 40 cathodes and to allow complete submergence. Operators fill both tanks with fresh water before pulling starts and add 1.5 pt of a sulphate-free detergent to the first, and 1 pt to the second tank. Racks of cathodes are submerged, loops and all in the first tank, and soaked 2 min to dissolve or loosen crystals which may have formed within the loop. After lifting, the rack is held for half a minute to drain, which is the chief function of the detergent as it gives a better run-off. Next is a quick rinse in the second tank and the water sprays on the unloading machine.

Crystalline material within the loop has proved most difficult to eliminate. While the shears cut off the loop and upper 10 pct of the cathode, experience has shown that sulphates, if not removed from the loops in the dip tanks, slowly dissolve and run back over the body of the sheets while still wet.

Iron originates from the same sources as sulphur. It has proved to be negligible in each shipment of electrodes to date. In refractories, iron control becomes more complex. Our experience has been that the iron content of refractories, provided they remain in place in either the hearth, walls, or roof, is not serious. However, iron is absorbed immediately by the bath if it becomes covered with spalled brick.

Chemically-bonded magnesite brick contains upwards of 10 pct total ferrous and ferric oxides. A chrome-magnesite roof, installed in June, carries somewhat more. Similar to sulphur, iron shows up in the first hours after relining. During the present campaign, however, and in spite of the higher iron in the roof brick, the June through September monthly composites contained 0.0015, 0.0012, 0.0014, and 0.0010 pct iron respectively, which are satisfactory values.

**Slag:** Slag formation varies directly with accidental or deliberate additions to the bath. Because of the very refractory character of the furnace lining, the skimmings should not be termed slag, as they consist of semifused crusts impregnated with copper shot and oxides. The analysis of the September skims was: Cu, 21.71 pct;  $\text{Fe}_2\text{O}_3$ , 2.86;  $\text{Al}_2\text{O}_3$ , 3.89;  $\text{SiO}_2$ , 20.00; CaO, 4.68; MgO, 33.28; and  $\text{Cr}_2\text{O}_3$ , 8.90. Ignoring the copper, the remainder corresponds to

an accidental mixture of roof and wall brick plus a minor amount of magnesite cement.

*Operation in General:* Both furnaces operate around the clock, except for one prearranged shut-down each week for repairs. This has gradually evolved as part of the routine and lasts for an hour or so.

The shift foremen enter on a special report delays in the furnace charging and the exact cause therefor. An average of a three-month period in the summer of 1950 indicates 1.6 pct lost time for mechanical breakdowns, 0.2 pct for electrical, 9.2 pct for slot cleaning, and 4.3 pct for operational delays including the weekly planned shutdown.

Copper build-up on the slot remains the largest single source of lost time, and modification of the slot is further projected to overcome the difficulty. Operating delays include slipping or adding electrodes, infrequent stoppages for skimming of the bath, and miscellaneous troubles.

The arc furnace is rated at 20 tons per hr. This rate has not been reached yet over an extended period; the best daily tonnages have been approximately 15 tons per hr, but over shorter periods the rated capacity has been approached.

A low power factor was obtained from the original 20-in. electrodes, and these were changed to 14-in. in December 1949, resulting in a rise in the power factor to over 70 pct. Characteristics of the larger electrodes were current surges, excessive agitation of the bath, a 50 to 60 pct power factor, but comparatively cool side walls and roof at any given bath temperature, and slightly less power consumption per ton melted. The smaller electrodes reduced current surging, and raised the power factor, but the walls and roof were relatively hotter for the same metal temperature, and the electrodes operate at low red heat between the clamps and the roof ring because of increased IR loss.

Electrode consumption in May, August, and September 1950, averaged 3.96, 4.20, and 3.96 lb per ton respectively. The intervening months were higher because weekend shut-downs raised wastage by consuming electrodes during holdovers when no copper was being melted.

*Arc Furnace Power Consumption:* During weekend holdovers in the summer of 1949, it was established that about 300 kw per hr was required to maintain the temperature in a full furnace bath when no cathodes were charged. This constant is the furnace heat loss, and continues at all times; therefore, on a per ton basis it is proportionally more or less according to the casting rate. At 5 tons per hr the loss, expressed as power, would be 60 kw-hr per ton, 30 kw-hr per ton for 10 tons, and 20 kw-hr per ton at 15 tons melted per hr.

According to the best thermal data,<sup>2</sup> molten copper at 2300°F contains 182.8 lb cal per lb, which is equivalent to 192.8 kw-hr per ton. If the heat loss input of the last paragraph is added, it gives 253 kw-hr per ton for 5 tons per hr, 223 for 10 tons, and 213 for 15 tons.

These figures are somewhat low on a current operating basis for two reasons. First, heat losses were based on a new furnace lining and roof, and the caloric loss will be higher with an old lining or thin roof. Second, they were also based on 20-in. electrodes, and as the 14-in. operate at low red heat

above the furnace roof, this IR loss would increase the 300 kw per hr loss. Power consumption currently ranges between 250 and 280 kw-hr per ton melted, depending on the casting rate.

*Temperature Control:* A multiplicity of temperature readings are recorded automatically or read at stated intervals and entered on the shift reports. Three equally spaced, dial, gas thermometers are inserted through the arc furnace shell to contact the brick slightly below the metal line. Under the charging slot, shell temperatures are taken once a shift with a surface-contact thermocouple. A thermocouple is embedded in the brick bottom at the apex of the inverted dome of the hearth. The temperature at this position is also recorded once a shift.

All the foregoing were installed originally to signal bottom failure, and the foremen record the temperatures at the start of each shift. To date, no failure has occurred, and the readings have had little significance. At the end of the last preheating in June 1950, the thermocouple in the bottom of the hearth recorded 320°F, rose to 400° in two weeks, and reached 420° after five months.

A radiation pyrometer with the internal end of the target tube flush with the inner face of the arc furnace wall automatically records the wall temperature. This was installed as a safeguard immediately after observing that the 14-in. electrodes gave significantly hotter walls. The normal range lies between 2400° and 2500°F, but a limit of 2600° was established, and the power input is reduced when temperatures exceed the latter figure.

Arc furnace operators insert an immersion thermocouple in the tap hole every 15 min, and the result is recorded automatically on a chart. Typical readings over any one day would be a maximum of 2380°F, minimum of 2250°, and average of 2310°.

At the induction furnace a second radiation pyrometer, sighted on a tube terminating in the bath, records metal temperatures and automatically controls the power input. This is checked manually once an hour with an immersion thermocouple, and the normal range lies between 2180° and 2250°F.

During a 57-hr layover in 1949, it was established that a power input of 49 kw per hr was necessary in order to hold the induction furnace bath at an even temperature, with neither metal input nor output. The two operating taps are 30 and 65 kw-hr, and theoretical calculations based on the heat loss and a 15 ton per hr at 2300°F input, show that the lower tap would give a constant bath temperature drop of 14°F, and the higher a pick up 6°F. The metal, leaving the induction furnace is, therefore, in the neighborhood of 2200°F.

The function of the core-bushing thermocouple at the primary induction loop has been described. In addition, two gas thermometers are inserted in the cooling-fan discharge of the same bushing, and air temperatures are noted as an extra precaution.

*Dust Loss:* Copper, even at conventional reverberatory temperatures, has a slight vapor pressure, and under the much hotter arc, it becomes appreciable. A wet cyclone treats gases from the roof vent and charging slot. Total vaporization amounts to approximately 4 lb of copper per ton melted, of which the scrubber recovers about 85 pct. The lost fume is largely around one micron in diameter, and a small bag house is in process of being installed to collect it. The recovered dust is recharged into the reverberatories, as it is largely pure cuprous oxide.

# Metallographic Techniques for High Purity Aluminum

by Italo S. Servi and Nicholas J. Grant

**S**PECIAL polishing and etching techniques were developed during an investigation of the high temperature mechanical properties of high purity aluminum (99.995 pct Al).<sup>\*</sup> Electrolytic polishing was done successfully in the following electrolyte: 5 ml perchloric acid (72 pct), and 95 ml glacial acetic acid.

No special precautions need be taken during the preparation of the electrolyte since no appreciable heat of mixing is evolved. Although the electrolyte is not an explosive, it is recommended that Jacquet's safety rules<sup>1</sup> be followed during the polishing operation.

A voltage of 25 to 60 v gives a good polish in about 2 min at room temperature after preparation on 3/0 metallographic paper. Most of the grain boundaries are visible under the microscope after polishing. Since the current is controlled essentially by the resistance of the bath, it is necessary to keep the anode-to-cathode distance as constant as possible.

Fig. 1—High purity aluminum. Electrolytic polish and etch as described in text. X15.

Fig. 2—High purity aluminum. Electrolytic polish in perchloric-acetic acid. a (left)—Partial "galvanic" etching in hydrochloric acid. Polarized light. X50. b (center)—Etched in modified Lacombe

Accordingly, polishing of irregularly shaped pieces will be difficult. A cooling bath and a stirring system are advisable in order to keep the temperature of the bath uniform and constant.

Coarse-grained samples can be macroetched in a few seconds by lowering the voltage below 10 v. This is done after electrolytic polishing, without removing the sample from the bath, Fig. 1. The specimen can be repolished in less than 1 min by raising the voltage above 25 v.

The "galvanic etching" technique, which has

been described elsewhere,<sup>2</sup> was found to be helpful not only for macroetching, but also for microetching coarse-grained specimens. In fact, the different orientations of adjacent grains provide good contrast at the grain boundaries, when the sample is observed under polarized light.

If the specimen is only partially etched, Fig. 2a, the grain boundaries can be located without completely destroying the appearance of the surface of the specimen. The unetched surface appears black under polarized light. Excellent color contrast is obtained by using a "sensitive tint" plate in the optical system of the microscope. In this case, the unetched surface has a magenta color, while the etched part of the sample assumes different colors varying from green to brown, according to the orientation of the grains.

Etch pits were produced on high purity aluminum by using the technique suggested by Lacombe and Beaujard.<sup>3</sup> Good results also were obtained by substituting 70 pct nitric acid for the fuming nitric acid recommended. This gave an etching reagent of the following composition: 70 ml nitric acid (70 pct), 50 ml hydrochloric acid (37.5 pct), and 3 ml hydrofluoric acid (48 pct). An example of the results is shown in Fig. 2b. The outline of the etch pits is revealed sharply if the specimen is observed under

reagent for 30 sec at 9°C. X1000. c (right)—Etched in Lacombe reagent for 30 sec at 9°C. Polarized light. X500. Area reduced approximately 75 pct for reproduction.

polarized light, as shown in Fig. 2c.

These metallographic techniques are not suitable for the examination of commercially pure (2S) aluminum.

## Origin of the Cube Texture in Face-Centered Cubic Metals

by Paul A. Beck

THE occurrence of the (100) [100] or "cube" texture upon annealing of cold-rolled copper has been much investigated.<sup>1</sup> The conditions favorable for its formation were found to be a high final annealing temperature<sup>2</sup> or long annealing time,<sup>3</sup> a high reduction of area in cold rolling prior to the final anneal,<sup>2</sup> and a small penultimate grain size.<sup>4</sup> The effects of penultimate grain size and of rolling reduction were found by Cook and Richards<sup>4</sup> to be interrelated in such a way that any combination of them giving lower than a certain value of the final average thickness of the grains in the rolled material leads to a fairly complete cube texture with a given final annealing time and temperature. Also, according to the same authors, at a higher final annealing temperature a larger average rolled grain thickness, i.e., a lower final rolling reduction, is sufficient than at a lower temperature. These somewhat involved conditions can be understood readily on the basis of recent results obtained at this laboratory.

Hsun Hu was able to show recently by means of quantitative pole figure determinations that the rolling texture of tough pitch copper, which is almost identical with that of 2S aluminum,<sup>5</sup> may be described roughly as a scatter around four symmetrical "ideal" orientations not very far from (123) [112]. In the case of aluminum, annealing leads to retention of the rolling texture with some decrease of the scatter around the four "ideal" orientations, and to the appearance of a new texture component, namely the cube texture.<sup>6</sup> A microscopic technique, revealing grain orientations by means of oxide film and polarized light, showed that the retention of the rolling texture is achieved through two different mechanisms operating simultaneously, namely "recrystallization in situ," and the formation of strain-free grains in orientations different from their local surroundings, but identical with that of another component of the rolling texture. Thus, a local area in the rolled material, having approximately the orientation of one of the four "ideal" components of the texture, partly retains its orientation during annealing, while recovering from its cold-worked condition, and it is partially absorbed at the same time by invading strain-free grains of an orientation approximately corresponding to that of another "ideal" texture component. The reorientation here, as well as in the formation of the strain-free grains of "cube" orientation, may be described as a [111] rotation of about 40°, see Fig. 1 of ref. 6. The preferential growth of grains in such orientations is a result of the high mobility of grain boundaries corresponding to this relative orientation.<sup>7, 8</sup>

It appears very likely that in copper the mechanism of the structural changes during annealing is similar to that observed in aluminum (except for the much greater frequency of formation of annealing twins in copper). In both metals the new grains of cube orientation have a great advantage over the

new grains with orientations close to one of the four components of the rolling texture. This advantage stems from their symmetrical orientation with respect to all four retained rolling texture components of the matrix; they are oriented favorably for growth at the expense of all of these four orientations. As a result, the growth of the "cube grains" is favored over the growth of the others, as soon as the new grains have grown large enough to be in contact with portions of the matrix containing elements of more than one, and preferably of all four component textures.

It is clear that this critical size is smaller and, therefore, attained earlier in the annealing process if the structural units, such as grains and kink bands, representing the four matrix orientations are smaller, i. e., if the average thickness of the rolled grains is smaller. Hence, for a given annealing time and temperature, a smaller penultimate grain size and a higher rolling reduction both tend to increase that fraction of the annealing period during which the above condition is satisfied. Consequently, the percentage volume of material assuming the cube orientation increases. The same is true also for increasing time and temperature of annealing when the penultimate grain size and the final rolling reduction are constant, since the average size attained by the new grains during annealing increases with the annealing time and temperature. For the same reason, at higher annealing temperatures a given volume percentage of cube texture can be obtained with larger rolled grain thickness (larger penultimate grain size, or smaller rolling reduction) than at lower annealing temperatures. The well-known conspicuous sharpness of the cube texture may be interpreted as a result of the fact that selective growth of only those grains is favored that have an orientation closely symmetrical with respect to all four components of the deformation texture and exhibit, therefore, a high boundary mobility in contact with each.

The effect of alloying elements in suppressing the cube texture, as described by Dahl and Pawlek,<sup>9</sup> appears to be associated with a change in the rolling texture. For face-centered cubic metals, such as copper, which do exhibit the cube texture upon annealing, the rolling texture is always of the type described above, i. e., scattered around four "ideal orientations" of approximately (123) [112]. The addition of certain alloying elements, such as about 5 pct Zn or 0.05 pct P in copper, has the as yet unexplained effect of changing the rolling texture into the (110) [112] type. This texture consists of two fairly sharply developed, twin related components. In such cases, as in 70-30 brass and in silver, the annealing texture again is related to the rolling texture by a [111] rotation of about 30°, however, because of the different rolling texture to start from, it has no cube texture component. At higher temperatures, both in brass<sup>10</sup> and in silver,<sup>11</sup> grain growth leads to a further change in texture: A [111] rotation of the same amount, but in reversed direction, back to the original rolling texture.

P. A. BECK, Member AIME, is Head, Department of Metallurgy, University of Notre Dame, Notre Dame, Indiana.  
TN 80E. Manuscript, March 12, 1951.

In summary, it may be stated that the oriented growth theory of annealing textures readily explains, at least qualitatively, the various conditions and their interrelations thus far described in the literature, that affect the formation of the cube texture.

### Technical Note

## Theory of Annealing Textures

by Paul A. Beck

IN several recent investigations<sup>1-4</sup> considerable evidence was accumulated to show the predominance in various face-centered cubic metals of a certain relative orientation, corresponding to a rotation of 30° to 40° around a  $[111]$  axis, between a matrix with a strong single orientation texture and grains growing in this matrix.\* This relative orientation was found to occur both in recrystallization and in coarsening, "secondary recrystallization", so that one is inclined to look for an explanation applicable in both cases.

The abundance of growing grains in the described orientations proves that suitable "nuclei" are present in the matrix material and that they have the capacity to grow. The scarcity of growing grains in other orientations may be explained in one of two ways. Either the number of nuclei or the rate of growth must decrease strongly for orientations deviating from that predominating among the growing grains, Fig. 1. Both the "oriented nucleation" and the "oriented growth" theory found support in the literature. Because the frequency of nuclei as a function of orientation is in most instances not amenable to direct experimental investigation, a definitive decision is difficult to achieve. However, it is now known with great certainty that the rate of boundary migration is strongly dependent on the relative orientation of the two grains meeting at the boundary and that the orientation favored by high boundary mobility closely corresponds to that predominating in most cases of recrystallization and coarsening.<sup>5</sup> Thus, it was found that, in general, the mobility is very low for boundaries between grains of nearly identical orientation, or for coherent twin boundaries. On the other hand, the boundaries between two grains of a relative orientation corresponding to a  $[111]$  rotation of 30° to 40° have the highest mobility in face-centered cubic metals. If a large variety of nucleus orientations are produced

Fig. 1—Grain boundary mobility (solid line) and frequency of nuclei (dotted line) as a function of orientation according to (a) oriented growth theory and (b) oriented nucleation theory.

artificially by means of a highly inhomogeneous local deformation, nuclei close to the above orientation are found to grow fastest.<sup>2-5</sup>

In view of this evidence and of the fact that the preferred orientation relationship is the same in recrystallization and in coarsening, the oriented growth theory appears by far the more promising one. Since the origin of nuclei in primary recrystallization is certainly different from that in coarsening, the occurrence of the same orientation relationship in the two processes would be difficult to explain on the basis of oriented nucleation. Other advantages of the oriented growth theory are its capability of accounting for the often observed sharpening of the texture in coarsening,<sup>6</sup> and its suitability for explaining the role in the formation of the "cube texture" of the most important variables, such as the degree of rolling, the penultimate grain size, and the time and temperature of the last anneal.<sup>7</sup> No similarly consistent explanation of all these effects has ever been offered in terms of oriented nucleation.

An important problem in connection with the oriented growth theory is the following: In the cubic crystal system there are four  $[111]$  axes and

P. A. BECK, Member AIME, is Head, Department of Metallurgy, University of Notre Dame, Notre Dame, Indiana.  
TN 81E. Manuscript, March 21, 1951.

\* In a hexagonal close-packed metal, zirconium, for which sufficiently good data are available,<sup>12</sup> the reorientation upon recrystallization corresponds to a rotation of 30° around the basal plane normal. Therefore, it may be concluded that in both face-centered cubic metals and in hexagonal zirconium the reorientation in recrystallization corresponds to a rotation around the normal of a close-packed plane. In both cases the new orientation lies about half way between two orientations with low grain boundary energy, where the grain boundary energy may be assumed to have a maximum.

Fig. 2—Grain boundary mobility (solid line) and frequency of nuclei (dotted line) as a function of orientation according to the oriented growth theory. Certain orientations with high boundary mobility do not appear in the texture (a) because of scarcity of nuclei and (b) because the relative maxima of mobility have different values for the various crystallographically "equivalent" favorable orientations.

the  $30^\circ$  rotation around each of these can be carried out in two directions; there are, therefore, eight crystallographically equivalent orientations of the type required by maximum boundary mobility. Out of these, in most cases of recrystallization or coarsening, only one or two actually are observed to occur. The question is then whether it is possible to explain this discrepancy in terms of the oriented growth theory. Let  $a$ ,  $b$ , and  $c$  in Fig. 2a represent schematically three of the crystallographically equivalent orientations with high boundary mobility. If the orientation distribution of nuclei is fairly uniform (line I), all three orientations may be expected to occur in the recrystallization texture. An asymmetrical nucleus distribution (line II), which in itself would not give rise to a well-defined texture in the sense of oriented nucleation (compare with Fig. 1b), might nevertheless give the desired selection from among the eight crystallographically equivalent orientations of high boundary mobility. Another possible answer to the above question is that the orientations  $a$ ,  $b$ , and  $c$  strictly speaking are not crystallographically equivalent, since a deformation texture or a recrystallization texture, no matter how sharply developed, does not possess the symmetry of a corresponding ideal single crystal. Thus, the mobility maxima at  $a$ ,  $b$ , and  $c$  may have quite different values, favoring certain ones among the "equivalent" orientations, Fig. 2b, regardless of nucleus distribution.

It was observed by Burgers and Basart<sup>8</sup> that the recrystallized grains growing in a slightly deformed single crystal of aluminum, in contrast to those formed after heavy deformations, do not exhibit a well-developed texture. The question arises how this behavior can be reconciled with oriented growth. It has been pointed out<sup>5</sup> that the large scatter of orientations in this case may be a result of scarcity of nuclei in all of the orientations favored by high boundary mobility, see line III in Fig. 2a. It is indeed quite probable that an annealing texture does not develop here, because the lack of suitable nuclei prevents oriented growth from becoming operative. This state of affairs in no way affects the general conclusion that annealing textures, when they do occur, are the result of oriented growth.

What is the physical basis for the orientation dependence of boundary mobility? In a previous publication<sup>5</sup> the hypothesis was advanced that the mobility of a grain boundary depends on the rate of self-diffusion along this boundary. Furthermore, it was shown that at least qualitatively the correct orientation dependence of boundary mobility results from this hypothesis, if a plausible assumption is made concerning the rate of grain boundary self-diffusion as a function of the relative orientation of the grains meeting at the boundary. It was assumed that the rate of grain boundary self-diffusion decreases with decreasing grain boundary surface energy, because the atoms at the boundary are more tightly held in their positions. According to this assumption grain boundary self-diffusion is very slow at boundaries where the two grains have nearly the same orientation, and at coherent twin boundaries. This has been experimentally confirmed for tin by Fensham.<sup>9</sup> Analogous results were reported more recently by R. S. Barnes for the grain boundary diffusion of copper in nickel.<sup>10</sup> The above hypothesis, associating grain boundary mobility with the rate self-diffusion along the boundary, also received some independent confirmation recently. D. Turnbull<sup>11</sup> found that the free energy of activation for grain boundary migration in the coarsening of silver is nearly the same as the free energy of activation for grain boundary self-diffusion in the same material. It is quite likely that the elementary processes involved in atomic movements necessary for grain boundary migration are the same as those involved in grain boundary self-diffusion.

# Kinetics of Precipitation in Supercooled Solid Solutions

by G. Borelius

**A**BOUT the turn of the century, Gibbs' thermodynamic theory of heterogeneous equilibrium, on the one hand, and the experimental methods of thermal and microscopic analysis, on the other, gave to the physical metallurgist his first scientific tool, the equilibrium diagram. The classical equilibrium diagram of a binary alloy system shows the boundaries between ranges of homogeneous and heterogeneous equilibrium in their dependence of concentration and temperature. A homogeneous solid solution which on cooling passes such a boundary is assumed to precipitate, forming a mixture of two phases with different concentrations.

The equilibrium diagram and the equilibrium theory, however, give no information about the time scheme of the process or the intermediate states passed during precipitation. For this reason it satisfies neither the practical need of the metallurgist nor the curiosity of the physicist. As a matter of fact, in the heat treatment of alloys for technical use the objective very seldom is the equilibrium state. Thus good mechanical properties of construction material are connected, for the most part, with some intermediate state. As these intermediate states are thermodynamically unstable, there is, from a theoretical point of view, always to be expected a decay of the good properties with time; and it is a matter also of practical interest to know whether this natural life time of a material is of the order of, say, ten or thousands of years. Thus, for many reasons, there is a current demand to complete our knowledge of equilibrium through knowledge of the kinetics of the precipitation phenomena. From the point of view of the physicist, the most interesting question in this case is whether there are any general laws governing the kinetics.

According to a generally accepted view, precipitation is ruled by two more or less independent phenomena, the formation of nuclei of a new phase and the growth of these nuclei. It is also commonly accepted that there is a tendency for the velocity of growth to increase with increasing temperature because of the increasing mobility of the atoms. There is also a tendency for the velocity of growth to decrease in the neighborhood of the two-phase boundaries. So far, however, very little is known quantitatively about this fundamental phenomenon in the case of solid metallic systems. In our laboratory attention has been directed especially toward the nucleation phenomena, and a series of measurements have been carried out with the guidance of a work-

ing hypothesis (based on experiences from previous work on order-disorder transformations in alloys) about the influence on the nucleation of thermodynamic potential barriers. However, before discussing the experiments, the theoretical ideas will be considered.

In a binary solid solution the arrangement of atoms on the lattice points approaches with increasing temperature a state of full randomness, as illustrated by the ball model of Fig. 1, that might represent a [111] plane of a face-centered alloy with 30 pct "black" and 70 pct "white" atoms. In reality the atoms are changing places continually with their neighbors so that the picture should rightly have been a moving one. On account of this thermal motion the concentration of black atoms within a certain group of, say, a hundred or a thousand lattice points fluctuates with time around the bulk concentration of 30 pct in a manner governed by statistical laws. With decreasing temperature two independent changes in this state grow more and more important. First, the mobility of the atoms decreases, and second, the forces between the atoms will have an increased influence on the fluctuations. In alloys with a tendency for precipitation, which are the concern of this lecture, the distribution function of concentration fluctuations will broaden, so that the relative probability of great local variations from the bulk concentration increases.

Fig. 2 gives an example of such a fluctuation. When the alloy is supercooled below the solubility limit into the range of two-phase equilibrium, the fluctuations will now and then at some point give rise to a state that resembles the equilibrium state and thus will form a stable nucleus that is capable of growing by diffusion processes. In discussions with colleagues and in the literature, I have often encountered the idea that three or four atoms of the dissolved metal could form a nucleus of the new phase. A look at the ball model might be enough to indicate that this cannot be true. If it were true, there should be nothing but nuclei, whereas we know from experiment that nucleation must be a rather rare occurrence. In fact we have, as will be mentioned later, certain reasons to believe that the nuclei are formed by fluctuations containing some hundreds of atoms, which should be the order of the number of black balls in the fluctuating group of the figure, if it were extended into three dimensions.

As a working hypothesis we have assumed that the fluctuations producing nuclei, though large and rare, still are ruled by the distribution laws of fluctuations of the supercooled solid solution in its initial state. Thus the probability of nucleation will be connected to the thermodynamic properties of the solid

Fig. 2 (right)—Ball model of a big concentration fluctuation in a solid solution.

solution itself. These properties in turn may be determined approximately from the equilibrium diagram, and it is possible to obtain a connection between the equilibrium diagram and the nucleation that might be examined experimentally.

Fig. 3 gives an outline of the theoretical relationships. The upper figure is the equilibrium diagram of a solid binary system such as Au-Pt or Au-Ni with a gap of solubility. The solid line is the limit of solubility. In the lower diagram, the curve  $F$  shows the free energy as a function of the concentration at a certain temperature  $T$ . Between the two contact points of the double tangent, the curve itself gives the free energy of the unstable, supercooled homogeneous solutions, whereas the tangent gives the free energy of the stable mixture of two phases. The part of the free energy that is of importance here may be written approximately:

$$F = U - TS \quad [1]$$

where  $U$  and  $S$ , the structural part of the energy and the entropy, are functions of the concentration  $x$  only, but not of the temperature  $T$ . The entropy is given approximately by:

$$S = R [x \ln x + (1 - x) \ln (1 - x)] \quad [2]$$

whereas  $U$  has to be determined analytically or graphically, so that the contact points of the double tangent at all temperatures fit to the empirical solubility limits.

The theory of fluctuations shows that the distribution of fluctuations is highly dependent on the second derivative of the free energy with respect

Fig. 3—Thermodynamic relations for a system with limited solubility.

to concentration, that is, on the curvature of the  $F$ - $x$  curve. If this curve bends upward, as it does on both sides within the gap of solubility, the free energy is increased locally by a fluctuation, and as the free energy always tends to a minimum, the fluctuations are repressed, the more the curve is bent. If the curve bends downward, as it does in the central part of the gap, the fluctuations are unrepressed and their distribution is undetermined. A retardation of the fluctuations and accordingly of nucleation therefore might be expected to start above a line, dashed in the phase diagram of Fig. 3, which is the locus of the inflection points of the isothermal  $F$ - $x$  curves. Van der Waals, who in the nineties pointed out this line as the lower limit of metastable equilibrium, called it the spinodal, a name that we will adopt in the following. Above this line the formation of a nucleus presupposes that a group of, say,  $n$  atoms passes a thermodynamic potential barrier, which under certain simplifying assumptions can be expected to be the maximum difference  $\Delta F$  between the  $F$ - $x$  curve and the tangent to the curve at a point corresponding to the concentration of the alloy concerned. The probability of nucleation might be given by the formula:

$$P = P_0 e^{-\frac{Q}{RT}} e^{-\frac{n\Delta F}{RT}} \quad [3]$$

where  $Q$  is the activation energy per mol for the change of place of the atoms. As to the number  $n$ , the theory so far cannot give any prediction either of its magnitude or its dependence on concentration or temperature; it has to be determined from experiment.

The growing nuclei will give rise to new types of

Fig. 4—Decrease of resistance during precipitation in a Pb-Sn alloy.

forces in the lattice and corresponding new types of potential energy. Frenkel, Becker, and others have made calculations on the basis of a special surface energy at the surface of the nucleus, and Gorsky, Mott, Nabarro, and others on the basis of internal strain caused by the different atomic distances in and outside the nucleus. In certain cases these strains probably will stop the growth of the nucleus at a submicroscopic size, which at least for the present seems to be a natural interpretation of the submicroscopic age-hardening phenomena. In other cases the nuclei break away from the lattice of the matrix and then are capable of growing by diffusion into crystals of microscopic or macroscopic sizes.

measurements at the temperature of precipitation itself, such as measurements of resistance, magnetic susceptibility, changes of volume, and changes of internal energy, the latter studied by the heat given off from the specimen. In our laboratory two methods have been employed for the most part: Resistometric measurements which are easy and often very useful, especially for the first orientation; and calorimetric measurements, which are less simple to perform, but give results that are more directly interpretable.

Fig. 9—Solubility limits, spinodal, and limits of retardation in the system Au-Pt.

ing the precipitation of nitrogen dissolved in  $\alpha$  iron. The heat of precipitation is rather small. If after the quenching from 172° to 94°C, the specimen had been insulated thermally, the total increase of temperature caused by the heat of transformation, evolving during some 50 hr, would have been 0.2°C.

Fig. 6 gives an idea of the present limits of the experimental possibilities of the calorimetric method. It describes evolution of heat during the precipitation of carbon from  $\alpha$  iron, ferrite. The specimen had been heated for some time at 348°C, where the solubility of carbon in the ferrite is about 2/10,000 of a percent by weight, and after quenching it was aged at 130°C. This temperature was chosen so that precipitation would be completed in the course of one day, which was the most convenient rate. In this case the specimen, if insulated during the precipitation, would have obtained an increase of temperature of only about 0.02°.

For these investigations we chose those systems of alloys that are simple and of greatest interest;

namely the systems Au-Pt and Au-Ni, which are the only known systems with full mutual solubility at high temperatures, and a gap of solubility at lower temperatures; the system Pb-Sn with a maximum solubility of 30 atomic pct Sn and a precipitation of nearly pure Sn; the system Al-Zn with a broadest range of solubility from 0 to 65 atomic pct Zn, also covering a eutectoid concentration; and the system Al-Cu which, being of great technical importance, has been investigated in many laboratories, so that our results could be compared with those of other investigators. We have also done some calorimetric work on the precipitation of nitrogen and carbon dissolved in  $\alpha$  iron.

The first system investigated in search of influences of thermodynamic potential barriers was the Au-Pt alloys. Results of resistivity measurements by Johansson and Hagsten on an alloy with 30 atomic pct Pt are shown in Fig. 7. Alloys which were cooled rapidly from above the two-phase range gave resistances on a nearly straight line in the resistance-temperature diagram. Further the figure shows the resistances after 1, 5, 10, 20, and 35 hr and after reaching equilibrium. Up to about 550°C the velocity of precipitation increases with the temperature owing to increased mobility of the atoms. Here, 400° below the solubility limit, a retardation sets in which, some 100° below the limit, is so strong that there is no appreciable change in resistance even after 35 hr, although the motion of the atoms must be expected to be very lively at this temperature.

Victorin has investigated a number of Au-Pt alloys in the same way. Plotting the logarithm of the reciprocal of the relative decrease of resistance in 10 min against the reciprocal of the absolute temperature, he obtained curves as shown in Fig. 8 with rather well defined lower limits of retardation.

Fig. 10—Decrease of resistance in an Au-Ni alloy with 28 atomic pct Ni during precipitation.

Fig. 11 (above)—Dependence on temperature of the rate of precipitation in an Au-Ni alloy with 28 atomic pct Ni.

Fig. 12 (right)—Solubility limit, spinodal, and limit of retardation in the system Au-Ni.

A careful redetermination of the two-phase boundary, the solid line in Fig. 9, made it possible to calculate the free energy and the spinodal, the dashed line. Within the limits of experimental uncertainty the limits of retardation coincide with the spinodal.

In the system Au-Ni, we have investigated quite thoroughly only one single alloy with 28 atomic pct Ni. A first series of measurements, going from higher to lower temperatures, gave the resistance temperature diagram I of Fig. 10, that was completed by the measurements of the equilibrium state from lower to higher temperatures. A later series, II, showed slower precipitation and a still later one, III, even lower velocity of precipitation. A plot of the logarithm of the reciprocal of the decrease of resistance during the first 30 min against the reciprocal of the absolute temperature, which gives a clearer view of the initial stage of precipitation, is shown in Fig. 11. The three rather parallel logarithmic curves can be interpreted as a sum of the logarithm of a factor decreasing with the increasing mobility of the atoms with increasing temperature, which gives the straight line in the diagram, and the logarithm of a retarding factor. The fact that the curves are parallel to each other in the logarithmic diagram seems to indicate that there are variations in the a priori probability of nucleation between the three states. In fact a

microscopic investigation showed that, at an intermediate stage of the precipitation process, the number of centers of the second phase was very different in different crystal grains. On the other hand, the lower limits of retardation, which appear rather sharply, are the same, about 460°C, in all three cases. Fig. 12 shows how this limit coincides with the position of the spinodal which was calculated from measurements of the solubility limit by Köster and others.

The system Pb-Sn has been studied with resistivity and calorimetric measurements. Fig. 13 shows the logarithm of the time for a decrease in resistance of 2 pct vs. the reciprocal of the absolute temperature for five concentrations. The probable positions of the lower limits of retardation are marked by arrows.

Fig. 14 shows the phase diagram with the experimental limits of retardation marked by crosses. The oblique cross is obtained from a calorimetric investigation. The upper dotted line is the spinodal

Fig. 13—Logarithms of times for a decrease of resistance of 2 pct vs. reciprocal of absolute temperature for Pb-Sn alloys.

Fig. 14—Limit and solubility, calculated spinodal, and limits of retarded precipitation in the system Pb-Sn.

calculated from the carefully redetermined two-phase boundary. As the available boundary line in this system is rather short, the calculation may be somewhat uncertain.

Calorimetric investigations also have given another type of information. Precipitation above about 100°C has, as shown in Fig. 15, given the total decrease of internal energy that could be expected from the phase diagram, whereas precipitation below 100°C has given only about half of the calculated decrease. There seems to exist below 100°C some intermediate, metastable state, the nature of which we have not discovered so far.

The three systems under discussion have a simple gap of solubility between two primary solid solutions. It was of special interest to try to test the working hypothesis also on a system with a eutectoid point. An imaginable system of this kind with full solubility at high temperatures is shown in Fig. 16, together with free energy curves for the eutec-

Fig. 15 (left)—Calculated and observed total heat of precipitation in Pb-Sn alloys.

Fig. 16 (right)—Thermodynamic relations for a system with a eutectoid point.

toid temperature  $T_2$ , a higher temperature  $T_3$ , and a lower one  $T_1$ , the parts of these curves for the supercooled solid solutions having a positive second derivative of the free energy are marked with thick lines. The locus of the inflection points, the spinodal, is the dashed line in the upper part of the figure. Although at the lower temperature  $T_1$  there is only one continuous gap of solubility, there are three ranges with positive second derivatives, one of them in the central part of the gap.

Unfortunately there is no known system of this type with an unbroken series of solid solutions at high temperatures. In the system Al-Zn, however, there is at least an unbroken solubility from pure Al to a bit on the other side of the eutectic concentration. In Fig. 17 the solid lines show the two-phase boundaries according to resistometric measurements by Fink and Willey completed by more detailed measurements of our own. The dashed line is the spinodal determined by graphical methods, in this case with some difficulty and uncertainty. The crosses are empirical lower limits of retardation determined by resistivity measurements, and the circles such limits determined by calorimetric investigations. The good agreement with the calculated spinodal may partly depend on good luck, as the results are in fact somewhat complicated.

In this system Guinier has observed at low temperatures a submicroscopic precipitation of the

Fig. 17 (above)—Solubility limits, calculated spinodal, lower limits of retarded precipitation, and supposed upper limit of the Guinier-Preston aggregates in the system Al-Zn.

Fig. 18 (right)—Phase limits and calculated spinodal in the system Al-Cu.

Fig. 19 (left)—Evolution of heat during precipitation in Al-Cu alloys at 225°C.

Fig. 20 (above)—Ratio of power  $P$  to heat  $Q$  still to be given off as a function of time in Al-Cu alloys at 225°C.

Guinier-Preston type. Unpublished results of thermal analysis from our laboratory have shown that homogeneous Al-Zn alloys, which are cooled rapidly and aged at low temperatures when heated at a rate of the order of  $1^\circ$  per min at higher temperatures, show an absorption of heat that was found to start rather sharply at the temperatures marked by oblique crosses in Fig. 17. It is most probable that the line drawn through these points in the diagram is the upper limit of the range of existence of the Guinier-Preston aggregates. It is of particular interest to observe that the retardation of the initial rate of precipitation, governed by the position of the spinodal, appears, as well, within and above this range. From our point of view this is understandable as fluctuations are supposed to be necessary for nucleation in all forms of precipitation.

Another system from which there are kinetic studies of precision to present is the system Al-Cu. The constitution diagram for the Al-side of the system is shown in Fig. 18. Al dissolves up to 5.5 wt pct Cu at  $550^\circ\text{C}$ . There are three known precipitates  $\theta$ ,  $\theta'$ , and  $\theta''$ .  $\theta$  has the composition  $\text{Al}_2\text{Cu}$  and is the stable precipitate at all temperatures below the two-phase boundary.  $\theta'$  is another, metastable, form of  $\text{Al}_2\text{Cu}$  appearing as an intermediate stage of the transformation below about  $385^\circ\text{C}$ .  $\theta''$  is a submicroscopic intermediate precipitate appearing below about  $200^\circ\text{C}$  and causing the well-known age hardening of the Al-Cu alloys. Its nature has been discussed on the basis of X-ray investigations on single crystals by Preston, Guinier, Jagodzinski and Laves, and others. The upper limits of the three states, as shown in the figure, were determined by thermal analysis at rising temperature. The spinodal, as calculated from the two-phase boundary, is represented by the dashed line down to the right in the figure.

In contrast to the alloy systems already reported, we have for the Al-Cu alloys no measurements to report for constant concentrations at varying temperatures crossing the spinodal. They would prob-

ably be rather difficult to perform in this range because of the rapid precipitation. But an attempt has been made to study the influence of the thermodynamic potential barriers on alloys with varying concentrations at three constant temperatures,  $225^\circ$ ,  $110^\circ$ , and  $20^\circ\text{C}$ . The measurements are made by the calorimetric method which is, in this special case, preferable to resistance measurements, the results of which are complicated and difficult to interpret. At  $225^\circ\text{C}$ , we have studied the precipitation of the  $\theta'$  phase in the range of retarded nucleation. The calorimetric power-time curves are shown in Fig. 19. They are of a simple form making it possible to follow the precipitation process from the beginning to the end. The total amounts of heat obtained by integration are, within the limits of the experimental uncertainty, in accordance with the values calculated from the phase boundaries.

For a discussion of the formation of the nuclei, it is convenient to consider, instead of the power  $P$

Fig. 21—Evolution of heat as a function of time in an alloy of Al with 4.5 wt pct Cu at  $20^\circ\text{C}$ .

itself, the quantity  $P/Q$ , where  $Q$  is the heat still to be given off.  $P/Q$ , which may also be written  $dQ/Qdt$ , is approximately proportional to the fraction of the atoms still in solution, which per unit of time go over to the precipitate and can be shown to be proportional to the number of nuclei per unit of mass. Fig. 20 gives  $P/Q$  as a function of time. It shows that the number of nuclei first increases linearly and then reaches a constant value. The initial slopes of the curves are relative measures of the probability of nucleation in the supercooled solutions and are, according to eq 3, related to the product  $n\Delta F$  of the number  $n$  of atoms necessary to form a stable nucleus and the thermodynamic potential barrier  $\Delta F$  which can be calculated. In fact we have found good agreement with theory for  $n = 120$ .

The precipitation at 20°C, which is known to give the submicroscopic Guinier-Preston aggregates and which has been studied on samples with concentrations in a range below or near the spinodal, where nucleation is unretarded, give quite another picture in the calorimetric power-time diagram. Because of the unretarded fluctuations and the small distances of diffusion, the first precipitation is so rapid that the concentration of Cu still in solution, which was 4.5 pct in the case of Fig. 21, had decreased to about 2 wt pct before the specimens after quenching had reached the steady state necessary for measurement. What was observed during the measuring series is dependent on the further formation of nuclei, which is more and more retarded as the concentration of the solution decreases and the thermodynamic potential barrier increases. As can be expected under such circumstances, the power-time diagrams, of which Fig. 21 gives an example, take on a hyperbolic form and are not very much different for the various alloys investigated which held from 2.5 to 5.5 wt pct Cu.

The aging at 100°C gives, as is also known from other investigations, a precipitation of the  $\theta'$  as well as the  $\theta''$  phase. The power-time curves, exemplified by Fig. 22, are first hyperbolic like the curves for 20°C but end with an exponential part like the curves at 225°C.

The calorimetric investigations on the precipitation of nitrogen and carbon from solutions of  $\alpha$  iron, of which three examples were given in Figs. 4 and 5,

Fig. 22 (left)—Evolution of heat as a function of time in an alloy of Al with 4.5 wt pct Cu at 100°C.

Fig. 23 (above)—Solubility limits in the logarithmic phase diagrams Fe-N and Fe-C.

are so far very incomplete concerning the kinetics of the phenomena. However, the measurements give a new determination of the solubility limits, which is independent of all chemical determinations of the solubility and which might be of some interest of its own.

In the case of nitrogen the evolution of heat was observed at 80° and 94°C in samples which were heated previously at various temperatures from 170° to 575°C in order to obtain equilibrium of solution and thereupon quenched to room temperature. In the case of carbon the measurements were made at 100° or 130°C and covered a range of equilibrium of solution from 350° to 700°C. From the experimental values of the total amount of heat determined at various temperatures, the solubilities may be calculated by means of simple thermodynamic relationships on the assumption that the heat of solubility is constant through the whole range of temperatures covered by our experiments; the accuracy of this assumption, however, for the present is difficult to estimate.

Fig. 23 shows the results on the phase diagrams of Fe-N and Fe-C. Instead of the usual diagrams, with concentration and temperature along the axis, a diagram is used with the logarithms of the atomic ratios N:Fe or C:Fe vs. the reciprocal of the absolute temperature. The advantage of this type of diagram is that the solubility limits for small concentrations approach straight lines.

The results obtained so far seem to indicate that there are besides the phase boundaries two things which have a marked influence on the precipitation and which are fundamental enough to make a part of the phase diagram, namely the spinodal and, at least in some cases, the upper limits of the ranges of existence of various metastable states, as for instance the Guinier-Preston aggregates. It has to be emphasized, however, that the attacks on the problem of understanding the kinetics of precipitation phenomena are still rather fumbling. So, in order to obtain a first simple outlook, we have passed by some important complicating factors, such as the special influences of grain boundaries and cold working and the decreasing rate of crystal growth with decreasing supercooling. Further, our calculations of the free energy from the phase boundaries are only a first rather rough approximation.

# Separation of Copper from Zinc by Ion Exchange

by Ernest J. Breton, Jr. and A. W. Schlechten

Experiments on the separation of copper and zinc ions by selective action of ion exchange resins showed the carboxylic type to be more effective than the sulphonic resins. The latter demonstrated a greater capacity over a wider pH range. Data show the effectiveness of resins as a means of concentration.

IN recent years the restrictions of stream pollution laws and the high price of metals have created an interest in ion exchange as a means for metal recovery. Some applications have proved successful. In Germany during World War II, 17 tons of copper per day were recovered from rayon mill wastes by means of ion exchange resins;<sup>1</sup> and for some time in this country a large ion exchange unit has been in operation for the recovery of copper from rayon waste water. The possibilities of applying ion exchange to the recovery of metals occurring in plating rinse water is particularly promising.

In most of these applications only the metal being recovered occurs in the waste. The ion exchange resins act merely as a means of concentrating the metals to a point where they can be recirculated. It would be highly desirable to use ion exchange as a means of not only concentrating but also of separating metals. With the exception of the impressive separations accomplished in connection with the atomic energy program, very little has been done on metal separations.<sup>2</sup> Therefore, an investigation was undertaken at the Missouri School of Mines and Metallurgy to determine if either of the two main types of ion exchange resins could be used to separate metal ions in solution. The selective removal of copper ions from a mixture of copper and zinc on carboxylic and sulphonic-type resins was investigated as a function of flow rate, pH, copper-zinc ratio, and concentration. It was shown that zinc can be separated from copper and that very large ratios of concentration can be obtained using ion exchange resins. Since ion exchange is relatively new to the field of metallurgy, a brief review of the subject will be included.

## Theory of Ion Exchange

A comprehensive theory for ion exchange has not been developed as yet, but the mechanisms are analogous to metathetical reactions:

R is the designation for the ion exchange resin. If a copper solution is passed over a resin bed in the sodium form, two ions of sodium will be released for every ion of copper removed. For the most part this reaction follows the laws of mass action and of electrical neutrality. Consequently, if an excess of sodium ions is passed over a bed containing copper,

E. J. BRETON, JR. was associated with Rohm and Haas Co., Philadelphia. A. W. SCHLECHTEN, Member AIME, is Chairman, Department of Metallurgical Engineering, Missouri School of Mines and Metallurgy, Rolla, Mo.

Discussion of this paper, TP 3072D, may be sent, 2 copies, to AIME by Sept. 1, 1951. Manuscript, Sept. 11, 1950; revision, Jan. 15, 1951. St. Louis Meeting, February 1951.

the reactions will be reversed, and the resin will be regenerated to its original form.

A few empirical rules governing the exchange reaction have been set forth: 1—In general ions with a high valence will replace ions with a lower valence. 2—Ions having higher activity coefficients have a higher replacement potential. 3—In a series of monovalent ions, those with the smallest radii of hydration will tend to replace those having larger radii of hydration. 4—Where ions are similar in most respects, those with the higher atomic weight sometimes will take precedence. This last rule is not as definite as some of the others. These rules apply to rather dilute solutions at moderate temperatures and assume all ions to be present in about equal concentrations. Higher concentrations and temperatures may in some cases reverse the normal exchange reactions.

Ion exchange materials are unique in that their efficiency increases as the concentration of the solution decreases. For many exchangers, most efficient operation is obtained at concentrations in the order of one thousandths of a percent. Most applications, though, are made in solutions containing considerably higher concentrations than this. Coste<sup>3</sup> has shown that ion exchange resins will remove aluminum and iron effectively from solutions of up to 10 pct chromic acid.

## Ion Exchange Resins

Ion exchange resins are insoluble, porous, resinous structures to which active groups have been attached. Active groups such as  $(-SO_3)^-$  and  $(COO)^-$  pick up cations; hence structures saturated with groups such as these are called cation exchangers. Structures saturated with groups such as  $(-NH_3)^+$  which pick up anions, are referred to as anion exchangers.

The resinous structure of necessity is resistant to strong acids, bases, oxidizing, and reducing agents, and most of the common organic solvents. An idea of the stability can be gaged from the fact that resins last for many years under constant use without detectable chemical or physical breakdown.

The ion exchange reaction is not confined to the surface of these synthetic resins. Its porous structure permits active groups in the center of a particle as well as those on the surface to remove ions. A high capacity resin such as Amberlite IR-120 will remove up to 3.3 lb Cu per cu ft of resin.

In this investigation several approaches to the problem of separating copper from zinc by ion exchange were considered. First, if a reagent could be found which would complex one of these metals and not the other, then by passing this reagent through a bed of exchanger containing copper and zinc, the

Fig. 1—Laboratory apparatus for ion exchange experiments.

metal that was complexed would be removed selectively. The rare earth metals have been separated in this manner.

Second, if an ion could be found which would replace only one of these two metals on the resin, then a separation could be made by eluting with a solution of that ion.

Third, if either copper or zinc could be complexed to an anion, then that anion could be picked up with an anion exchanger and the remaining cation could be removed with a cation exchanger.

Fourth, if the active groups of an ion exchange resin exhibited a strong preference for copper or zinc, then the two metals could be separated merely by passing a mixture of them through a column of exchanger.

Of these four possible methods for separating copper and zinc, the last one was considered to be the most practical. Accordingly, this study was limited to the investigation of the fractionation of copper and zinc by Method 4 on the two main types of cation exchangers commercially available.

### Equipment and Materials

Fig. 1 shows the apparatus used. The glass column containing the resin was 2.50 cm in diam and 100 cm long. The resin bed was supported by a layer of glass wool covered by 4 in. of 28-mesh Ottawa sand. The tubing and pinch valves were so arranged that the solutions in any of the reservoirs could be delivered to the upper or lower end of the column.

The effluent was removed by first bringing it back up to an open Y above bed level. The open Y served to prevent the bed from siphoning dry if the influent solution should become exhausted.

The fractionation of copper and zinc on the two types of cation exchangers, Amberlite IR-120 and Amberlite IRC-50, was studied. Amberlite IR-120 is a high capacity nuclear sulphonic-acid type ion ex-

changer, produced in the form of bead-like particles. It can withstand strong acids and bases even at high temperatures.

In this investigation Amberlite IR-120 was used in the hydrogen form. The sodium form of the resin was converted to the hydrogen form by treatment with 10 pct sulphuric acid. The exchange reaction with copper and zinc for this resin is:

Amberlite IRC-50 derives its exchange activity from carboxylic acid groups. It exhibits exceptionally high capacities in basic solutions and is regenerated efficiently with acids. This resin is supplied in the hydrogen form. On conversion to the sodium form it undergoes up to 100 pct expansion. To allow for this expansion the conversion from the hydrogen to the sodium form was accomplished by stirring sodium hydroxide into a slurry of resin and water. Since the hydrogen form of Amberlite IRC-50 has a slow exchange rate, several hours were allowed for equilibrium to take place. The exchange reaction with copper and zinc could be represented as:

### Procedure

Ion exchange operations are very simple since a run usually consists of only four steps: Exhaustion, regeneration, rinse, and backwash. This procedure was followed in all experiments.<sup>4-6</sup>

A typical experiment involved: 1—Exhaustion: The influent, consisting of an aqueous solution of copper and zinc, was passed through the column until the breakthrough point was reached; that is, the point at which traces of copper or zinc began to appear in the effluent. Periodic qualitative analyses were made to determine this point. After the breakthrough, the run was continued and the effluent was analyzed for copper and zinc. The curve resulting from a plot of zinc and copper concentration vs. volume of effluent was used to evaluate fractionation. These effluent curves will be discussed in some detail later. 2—Regeneration: The copper and zinc were removed from the saturated resin by passing a suitable amount of regenerating solution through the bed. With Amberlite IR-120, 10 pct sulphuric acid was used as the regenerant. Amberlite IRC-50, due to its inefficient exchange of copper for sodium, was regenerated in two steps. First, the copper and zinc were removed with 10 pct sulphuric acid and then the resin was converted back to the sodium form with 4 pct caustic. 3—Rinse: Water was passed through the bed until no more regenerant ions appeared in the effluent. 4—Backwash: In order to reclassify the resin and remove foreign matter, water was passed upflow through the column for 10 min. The flow rate was regulated to give a 75 pct bed expansion. The resin then was ready for the next cycle.

A colorimetric method of analysis was used for copper. For zinc the potassium ferrocyanide method employing uranyl nitrate as an external indicator was used.<sup>6</sup> Distilled water was employed for all backwashing and rinsing operations.

### Experimental Results

The separation of copper from zinc using both resins—Amberlite IRC-50 and Amberlite IR-120—

was studied as a function of: 1—Flow rate, 2—pH, 3—concentration, and 4—copper-zinc ratio. In the study of these variables, the sodium form of Amberlite IRC-50 and the hydrogen form of Amberlite IR-120 were used.

One of the most promising features of ion exchange is the high ratio of concentration which can be achieved. To demonstrate this a 0.005 N  $\text{CuSO}_4$  solution was concentrated on the carboxylic resin.

*Amberlite IRC-50 vs. Amberlite IR-120:* A very good fractionation of copper and zinc on the carboxylic resin, Amberlite IRC-50, was achieved. On the sulphonic resin, Amberlite IR-120, only a slight fractionation was obtained. In Figs. 2 and 3 the effluent curves for these two resins are given.

All of the zinc and copper were removed from the influent, and the sodium that was liberated passed on through the column. The amount of sodium appearing in the effluent was equivalent to the sum of zinc plus copper in the influent. As more influent passed over that part of the resin already exhausted, the copper in solution displaced the zinc. The displaced zinc then passed down the column and reacted with the first sodium resin with which it came in contact. This resulted in banding of the copper and zinc.

After 16 liters had passed through the column, the zinc had reacted with all of the sodium form of the

resin. The column was then divided into two bands, the upper half contained copper and the lower zinc. This was visible inasmuch as the copper color on the resin had progressed only half way down the column when zinc first appeared in the effluent.

When the resin became saturated with zinc, further zinc entering the column plus that displaced by the copper appeared in the effluent. The stoichiometric displacement of zinc by copper was evidenced by the fact that the zinc in the effluent at 22 liters was equal to the sum of the zinc plus copper in the influent. At 42 liters the column contained mostly copper—94 pct. Beyond 42 liters practically no further reaction took place between the influent and the resin.

The exchange mechanism for the sulphonic resin, Fig. 3, was similar to that of the carboxylic resin; however, both ions traveled down the column at approximately the same rate.

To evaluate these effluent curves quantitatively, the percentage recovery and percentage purity of zinc in the effluent was plotted against effluent volume. To arrive at the percentage recovery and purity, the areas under the effluent curves were measured and multiplied by an appropriate factor to give the grams of metal appearing in the effluent. Knowing the influent volume and concentration, the percentage recovery and purity could be calculated at any given volume. Thus:

Fig. 2—Fractionation of copper and zinc on Amberlite IRC-50, sodium cycle. Flow rate 0.005 ml per ml resin per min.

Fig. 3—Fractionation of copper and zinc on Amberlite IR-120, hydrogen cycle. Flow rate 0.11 ml per ml resin per min.

Fig. 4—Separation of copper and zinc on Amberlite IRC-50, expressed as percentage purity and recovery vs. volume of effluent.

$$\text{Recovery} = \frac{\text{Zinc recovered in effluent}}{\text{Total zinc to column in influent}} \times 100$$

$$\text{Purity} = \frac{\text{Zinc in effluent}}{\text{Zinc} + \text{Copper in effluent}} \times 100$$

In Fig. 4 the fractionation of copper and zinc on Amberlite IRC-50 is expressed in terms of zinc recovery and purity in the effluent. The effectiveness of this carboxylic resin in separating copper from zinc is indicated by the fact that 92 pct of the zinc was recovered in the effluent at a purity of 94 pct. Just as the purity and recovery of zinc in the effluent was increased, so the purity of the copper retained on the resin was increased over that in the influent. These results indicate that the carboxyl groups of Amberlite IRC-50 show a great preference for copper over zinc.

Amberlite IR-120 brought about a slight enrichment of zinc in the effluent. Apparently the sulphonic groups of this resin exhibit only a slight preference for copper.

Except for the effect of pH, the ensuing discussion will be limited to the performance of Amberlite IRC-50.

Fig. 5—Effect of flow rate on separation. Amberlite IRC-50, sodium cycle.

**Effect of Flow Rate:** The flow rate had a great effect on both the fractionation and capacity of the resin. The effectiveness of Amberlite IRC-50 was reduced at higher flow rates. In Fig. 5 the decrease in fractionation due to an increase in the flow rate is illustrated. The separation index used in this figure represents the percentage purity of zinc in the effluent when 50 pct of the zinc had been removed from the column. At a flow rate of 0.005 ml per ml of resin per min, a high degree of fractionation was obtained.

An increase in flow rate also impaired the capacity. At a flow rate of 0.1 ml per ml of resin per min the capacity was 0.22 g Cu per ml of resin compared to a capacity of 0.41 g Cu per ml of resin at a flow rate of 0.005 ml per ml of resin per min.

The effect of flow rate is due to the slow reaction rate between the carboxyl groups and copper and zinc. At high flow rates the copper and zinc ions are rushed through and do not have time to approach equilibrium conditions.

**Effect of pH:** Changes in pH had little effect on the fractionation of copper and zinc. It did, as mentioned, greatly affect the capacity of Amberlite IRC-50. In Fig. 6 the effect of pH on the two resins is illustrated. The effect of pH on Amberlite IR-120 was observed by varying the pH of the solution passing through the resin. With Amberlite IRC-50 the pH was varied by titrating NaOH into the acid form of the resin until the desired pH was reached. The influent pH was 5.0 in all cases. These curves mean

Fig. 6—Effect of pH on capacity

that Amberlite IR-120 can be used effectively at a pH down to and below 1.75. Amberlite IRC-50 on the other hand is very sensitive to pH. To treat solutions with a lower pH, this carboxylic exchanger should be fully regenerated using caustic. Amberlite IRC-50 acts like a weak acid; consequently it has a very high affinity for hydrogen ions. Amberlite IR-120 acts like a strong acid which is highly ionized; its affinity for hydrogen is low.

**Effect of Concentration and Copper-Zinc Ratio:** At a copper to zinc ratio of 1:1, variation in total concentration of copper and zinc between 0.01 and 0.1 normal had no effect on the fractionation of copper and zinc. Below a normality of 0.01 the fractionation,

if any change occurs, should improve. At what concentration above 0.1 normal the efficiency of the resin falls off was not determined.

The copper-zinc ratio, however, had a decided effect on the fractionation. Below a copper to zinc ratio of 1:1, copper was removed effectively from a solution of copper and zinc. On the other hand, as the ratio of copper to zinc increased above one, the complete removal of copper became more difficult. The good fractionation obtained at lower copper-zinc ratios indicates that it would be possible to remove traces or small amounts of copper from stronger solutions of zinc.

### Exchange Resins as Concentrators

The experiment to demonstrate exchangers as concentrators was made by passing an 0.005 N  $\text{CuSO}_4$  solution over a bed of Amberlite IRC-50 until the copper breakthrough in the effluent was reached. A 40 pct  $\text{H}_2\text{SO}_4$  eluting solution then was passed through the column and analyzed for copper. The elution curve is given in Fig. 7. Shortly after 100 cc of eluting solution had passed through, the solubility of  $\text{CuSO}_4$  was exceeded which resulted in the precipitation of  $\text{CuSO}_4$  in the ion exchange bed. The gradual decrease in concentration of copper towards the end of the elution probably was caused by the copper sulphate crystals going back into solution.

The ratio of concentration vs. percentage recovery for this experiment is given in Fig. 8. When 90 pct of the total copper had been recovered in the effluent,

Fig. 7—Elution of copper from Amberlite IRC-50 using 40 pct  $\text{H}_2\text{SO}_4$ .

the volume ratio of concentration was 625.

The high avidity of Amberlite IRC-50 for hydrogen ions makes very high ratios of concentration such as this possible. The regeneration efficiency using acids approaches 100 pct in most cases. That is, almost 100 pct of the hydrogen ions in the regenerating solution contribute to the replacement of copper ions on the resin. On the sulphonic type resins approximately 35 pct of the hydrogen ions in an acid regenerating solution are actively engaged in the exchange reactions.

### Conclusions

It is possible by means of ion exchange resins to remove metal ions from very dilute solutions and recover them in a concentrated form. This suggested the use of ion exchange in metallurgical recoveries. A survey of the literature revealed that little had been done in applying ion exchange to metallurgical problems. Although removal of ionic impurities has been investigated extensively in connection with

Fig. 8—Ratio of concentration vs. recovery with Amberlite IRC-50 used as a concentrator.

water softening, only limited work has been done on metal separations.

Since the metallurgist is concerned with the separation of metals as well as their concentration, an investigation of the selectivity of ion exchange resins was undertaken. The results of this work on the separation of copper from zinc may be summarized as follows:

1—A carboxylic-type resin can be used to effect the recovery of copper from a mixture of copper and zinc ions. The capacity of this type of resin was very high above a pH of 7; however, below a pH of 5 the capacity became too low for most uses. Consequently, the carboxylic resin would be advisable where a separation is desired.

2—A low degree of selectivity was obtained on the sulphonic resin. It did exhibit a high capacity under wide variation of pH and flow rates; therefore, this type of resin would be useful for the removal of ions under acidic conditions.

3—Ion exchange resins, especially the carboxylic type, can be used to concentrate ions from very dilute solutions.

It appears that there are several possible uses for ion exchange resins in metallurgy. They seem particularly suited to the recovery of metal ions from waste waters. Not only would the recovered metal be of value, but stream pollution could be prevented and possibly the water could be reclaimed.

What role ion exchange will play in the metallurgical field remains to be seen. It seems likely that through this unit process the range of metal recovery can be extended far beyond that obtainable by conventional methods.

# Ignition Temperatures of Magnesium And Magnesium Alloys

by

W. Martin Fassell, Jr.

Leonard B. Gulbransen

John R. Lewis

and

J. Hugh Hamilton

A simple reproducible method was developed for determining the ignition temperatures of magnesium and magnesium alloys and by this method magnesium and over 100 magnesium alloys were measured. The ignition temperature of magnesium was determined in  $O_2$ - $SO_2$ ,  $O_2$ - $N_2$  mixtures and in  $O_2$  from 0.166 to 10 atm pressure. The ignition temperature of magnesium is generally lowered by alloying and increased by an increase in oxygen pressure.

WITH the expanded use of magnesium alloys in industry, ignition temperatures are of considerable importance, especially in heat treating and for service at elevated temperatures. Magnesium alloys exhibit a relatively slow linear oxidation rate up to temperatures near the melting point.<sup>1</sup> At some critical temperature the rate of oxidation becomes extremely rapid. This high rate of oxidation is accompanied by the emission of light and additional characteristics suggesting a flame.

The literature concerning the ignition temperatures of magnesium and magnesium alloys is relatively incomplete and the values reported by various authors are not in agreement. The most probable reasons for this are: 1—The absence of a suitable definition of ignition, and 2—the need of a standardized method of determining the ignition temperatures of inflammable metals and alloys.

This paper is a report of work done under contract with the Technical Command, Chemical Corps, U. S. Army.

The exact date of the discovery of the fact that magnesium will ignite and burn is unknown. It is likely that H. Davey encountered this property of the metal during its preparation in 1808. The first reference in the literature specifically on ignition of magnesium is by Lenze, Metz, and Rubens.<sup>2</sup> They investigated the inflammability of certain magnesium alloys. Brown<sup>3-4</sup> reported that magnesium ribbon will ignite in air at 507°C by what was called the rising temperature method. Hartman, Nagy, and Brown<sup>5</sup> reported that magnesium powder ignites from 475° to 560°C depending on particle size. According to Guise, Mars, and Wilson<sup>6</sup> prolonged heating in air at 427°C of common casting magnesium alloy causes it to ignite. Samples of magnesium alloys were placed directly in the flame of a torch by Carapella and Shaw.<sup>7</sup> These investigators obtained some evidence of melting prior to ignition. For commercial magnesium, they reported an ignition temperature of 650°C. Their values varied from 450° to 800°C for magnesium alloys. Willmore and Peterson<sup>8</sup> studied the effect of air velocity, humidity, rate of heating, and foreign metal contact on the ignition temperature of magnesium. They conclude that melting is not a prerequisite for ignition and that the conditions which influence ignition are complex and difficult to analyze.

The only quantitative theoretical treatment of the ignition temperatures of magnesium and magnesium

alloys is that of Eyring and Zwolinski.<sup>9</sup> Following the ideas set forth by Pilling and Bedworth<sup>10</sup> in their discussion of the ignition of calcium metal, Eyring and Zwolinski concluded that a metal sample will ignite if the conduction of heat through the oxide film is insufficient to remove the heat produced at the metal oxide interface as a result of the oxidation reaction.

Actually, Constable,<sup>11</sup> Suzuki,<sup>12</sup> and others have shown that this condition exists at temperatures below the ignition temperature.

Eyring and Zwolinski state that as a result of inadequate loss of heat through the film, the temperature at the metal-oxide boundary will increase, accelerating the rate of the reaction. The progressive acceleration of the rate of oxidation will result in the vaporization of magnesium with subsequent ignition of the metal vapor.

The thermal energy lost by conduction from the sample can be equated to the thermal energy produced by the oxidation of the sample. This relationship is expressed by the equation:

$$\kappa \frac{(T - T_0)}{d} = \frac{\Delta H}{N} v \quad [1]$$

where  $\kappa$  is the thermal conductivity,  $v$  is the rate of oxidation,  $T$  is the temperature at the metal-oxide interface,  $T_0$  is the temperature at the outer surface of the film,  $d$  is the thickness of the oxide film,  $\Delta H$  is the heat of formation, and  $N$  is Avogadro's number. According to the proposed theory<sup>9</sup> ignition will occur at the instant the thermal balance represented by eq 1 is destroyed.

The reaction rate,  $v$ , from the Theory of Absolute Reaction Rates<sup>13</sup> may be written as:

$$v = C_s \frac{kT}{h} e^{-\epsilon/kT} \quad [2]$$

where  $C_s$  is the number of adsorption sites on metal atoms per sq cm,  $k$  is Boltzmann's constant,  $h$  is Planck's constant,  $T$  is the temperature °K,  $\epsilon$  is the activation energy. Substituting eq 2 in eq 1 it becomes:

$$\kappa \frac{(T - T_0)}{d} = C_s \frac{kT}{h} e^{-\epsilon/kT} \frac{\Delta H}{N} \frac{AM}{AF} \quad [3]$$

where  $AM/AF$  represents a roughness factor. Rewriting eq 3 in a more convenient form:

$$T_0 = \left( 1 - C_s \frac{kd\Delta HF}{\kappa h N} e^{-\epsilon/2T} \right) T \quad [4]$$

and substituting in the following values in eq 4:

$$\begin{aligned} C_s &= 1.1 \times 10^{15} \text{ Mg atom per sq cm} \\ k &= 1.38 \times 10^{-16} \text{ ergs per } ^\circ\text{K} \\ \Delta H &= 146 \text{ kg-cal per mol} \\ F &= AM/AF = 16 \\ h &= 6.62 \times 10^{-27} \text{ erg sec} \\ \kappa &= 2.8 \times 10^{-4} \text{ cal cm } ^\circ\text{C}^{-1} \text{ cm}^{-2} \text{ sec}^{-1} \\ N &= 6.02 \times 10^{23} \text{ atoms per mol} \\ E &= 42.7 \text{ kg-cal per mol for 1.78 pct Al-Mg alloy, from ref. 1.} \\ E &= 50.5 \text{ kg-cal per mol for Mg from ref. 1.} \end{aligned}$$

Eyring and Zwolinski calculated the values for the ignition temperature of magnesium shown in Table I.

Thus, the theory of Eyring and Zwolinski indicates that the ignition temperature is dependent on

Fig. 1—Typical ignition temperature determination.

the oxide film thickness. As will be shown later, this theory does not agree with the experimental results obtained by the authors in that the time delay experiments indicate that the ignition temperature of magnesium is independent of the nonprotective oxide film thickness. In addition, the thermal equilibrium represented by eq 1 is violated at temperatures below the ignition temperature. The Constable effect would be impossible under the imposed conditions of this equation. As will be shown later, this theory does not explain satisfactorily the experimentally observed fact that the ignition temperature of magnesium is pressure dependent.

From the literature pertaining to the ignition temperatures of magnesium and magnesium alloys, as cited above, it is obvious that none of the experimental values agree and that there is some conflict as to the exact definition of the ignition temperature.

### Experimental Procedure

In this investigation, the ignition temperature is defined as the "explosion temperature," that is, the temperature at which the rate of oxidation suddenly becomes extremely rapid and a "flame" appears. From preliminary experiments it was found that the following method was satisfactory for determining the ignition temperature of magnesium and magnesium alloys. A thermocouple was placed in intimate contact with a small magnesium sample. The sample was heated in an electric furnace at a specified rate in an oxygen atmosphere. The heating curve of the sample shows two distinct branches. A typical curve is shown in Fig. 1. Branch a-b corresponds to the heating of the sample by the furnace and b-c to the heating of the sample by ignition.

From actual observation, it was found that the point b corresponds very nearly to the temperature at which a flame is propagated. Point b then corresponds to the definition of ignition temperature. This definition was adopted because the values of the ignition temperatures are reproducible (i.e.,

Table I. Experimental Vs. Calculated (Eq 4) Ignition Temperatures of Magnesium and Magnesium Alloys

| Pure Mg     | $1 \times 10^{-1}$       | 618                  | 623                       |
| Pure Mg     | $2 \times 10^{-1}$       | 595                  | 623                       |
| Pure Mg     | $5 \times 10^{-2}$       |                      | 623                       |

\* Leontis and Rhines<sup>1</sup> obtained a value of 548°C.

Fig. 2—Furnace used in ignition temperature experiments.

$\pm 5^{\circ}\text{C}$ ) on any given alloy composition. In addition, the ignition temperature is not influenced by complicating factors such as the Constable effect<sup>11</sup> ("self heating" of the sample); size of sample, within reasonable limits; rate of flow of oxygen; time of exposure; and rate of heating.

#### Measurement of Ignition Temperature

The alloy samples were melted in a small induction furnace, cast in a preheated split steel mold ( $\frac{1}{2}$  in. diam  $\times$  3 in.) and turned on a lathe to 0.375 in. and cut into  $\frac{1}{2}$  in. lengths. Power cross feeds of 0.0018 in. per revolution were used to insure uniform surface conditions on all samples. A hole was drilled coaxially  $\frac{3}{8}$  in. deep with a No. 47 wire gage drill to provide a well for the thermocouple.

The hot junction of the thermocouple was inserted into the well of the alloy sample to be tested and the lead wires doubled back to form a U-shaped cradle so that only the junction was in contact with the sample.

Throughout the investigation the ignition temperatures were determined by measuring the temperature of the sample with a chromel-alumel thermocouple (28 gage) connected to a Leeds and Northrop Micromax recorder.

The schematic arrangement of the furnace (Hoskins Type FA120) with the sample in position is shown in Fig. 2. This equipment was used in all ignition temperature determinations in oxygen, oxygen-nitrogen, and oxygen-sulphur dioxide mixtures at atmospheric pressure.

With the sample in position, the flow of pure oxygen or oxygen mixture was started through the bottom of the furnace and adjusted to a rate of 250 ml per min. (The ignition temperature of pure

magnesium was found to remain constant at flow rates from 50 to 500 ml per min.)

After 5 min the furnace was turned on (voltage to furnace held constant at 100 v, i.e. 83 pct rated voltage). Heating was continued until the recorder showed a sharp increase in rate of temperature rise, indicating ignition. After completion of the test, the tangential intersection of the two branches of the heating curve was plotted and the temperature of ignition evaluated.

Oxygen was used for the majority of the ignition temperature determinations. While this does not duplicate the conditions during heat treatment, it does provide comparative results between magnesium and its alloys. When air was substituted for oxygen, somewhat erratic temperatures were obtained, but with oxygen no such difficulty occurred and usually the mean variation did not exceed  $2^{\circ}\text{C}$ .

The ignition temperatures of the following systems have been determined: Mg, Mg-Ag, Mg-Bi, Mg-Co, Mg-Ca, Mg-Ni, Mg-Sb, Mg-Pb, Mg-Zn. In addition a number of other binary alloys have been studied in certain regions as well as a number of

nition temperatures of magnesium in mixtures of oxygen and sulphur dioxide are given in Table IV.

### Delayed Ignition of Magnesium Below Normal Ignition Temperature

As pointed out above, the theory of ignition of magnesium as proposed by Eyring and Zwolinski<sup>9</sup> indicates that the ignition temperature is dependent upon the thickness of the oxide film on the sample. The following series of experiments were conducted to determine the validity of this theory.

**Experimental Procedure:** Preliminary experiments on the ignition of magnesium with prolonged heating showed that the Constable effect<sup>11</sup> (a spontaneous rise in temperature as a result of heat evolved by the oxidation process) may occur at temperatures considerably below the ignition temperature. Due to this spontaneous rise in tempera-

Table V. Time Necessary for Magnesium to "Self Heat" to the Temperature of Ignition

| Sample Number | Constant Furnace Temperature, °C | Sample Temperature at Which Ignition Occurred | Time Interval to Ignition Temperature, Min |
|---------------|----------------------------------|-----------------------------------------------|--------------------------------------------|

ture, it is necessary to control the temperature of the furnace or bath by a thermocouple in the furnace wall or very near to it. Also, the sample temperature must be measured by a separate thermocouple, since its temperature will be above the furnace temperature at any finite time after the introduction of oxygen.

Fig. 5—Pressure ignition furnace.

The equipment used to conduct these experiments was designed to avoid the possible difficulties from the Constable effect. The apparatus is shown schematically in Fig. 4.

The furnace was a Hoskins Type FA 120, the same type as used in the standard ignition determination. The furnace temperature was controlled by means of a thermocouple placed very near the furnace wall and connected to a Leeds and Northrop Micromax temperature controller. The bottom section of the heating chamber was filled with Ottawa sand, *E*, to allow the incoming gases to reach the furnace temperature. A small circular base plate of stainless steel, *C*, was fitted with the sample thermocouple and the sample, *D*, and made so that the bell, *B*, was placed in the sealing ring of the base plate completely covering the magnesium sample. While the furnace was cold, the helium\* flow into the interior of the bell was started to prevent oxidation and continued until temperature equilibrium between the sample and the furnace walls was reached. At the same time oxygen was passed into the heating chamber. When equilibrium was established, the flow of helium was stopped and the bell raised to allow the oxygen to come in contact with the magnesium sample. Time was counted from this instant. When ignition occurred the elapsed time interval was recorded. The results of these experiments are shown in Table V.

#### Change in Ignition Temperature of Magnesium as a Function of Oxygen Pressure

The object of these experiments was to determine if the ignition temperature is a function of oxygen pressure. These data may indicate the type of reaction involved in ignition of the magnesium sample.

**Experimental Procedure:** The procedure for determining the ignition temperature using the special pressure furnace, Fig. 5, is as follows: The thermocouple wires were led through the threaded steel plug, *A*, and the packing glands, *B*. The packing, moistened asbestos fiber, was placed in the conical wells in plug, *A*, and the gland nuts, *B*, screwed into place. The sample, *L*, was suspended by the thermocouple wires and the assembly screwed into the furnace top, *C*, sufficiently tight to seal, *A* and *C*, by means of the lead gasket, *H*. Oxygen was then admitted through the inlet tube, *G*, from the oxygen cylinder via a reduction valve which reduced the pressure to a maximum of 200 psi.

The oxygen passed through the Ottawa sand zone, *I*, and the sample chamber, *B*, of the electrically heated furnace, *F*. The valve, *K*, on the outlet pipe, *J*, was opened and closed intermittently until all air was purged from the system. Valve *K* then was closed and the pressure adjusted to the desired value. The thermocouple wires were connected directly to a Brown recording potentiometer. Heating was then started following the same program as for the standard ignition determination.

The data obtained in the study of the effect of oxygen pressure on the ignition temperature of magnesium is shown in Table VI and Fig. 6.

#### Lowering Ignition Temperature of Magnesium

The lowering of the ignition temperature of magnesium by contact with other metals has not been investigated thoroughly. Preliminary experiments

\* Helium, special purity (no dew point). Furnished through the courtesy of S. R. Zimmerley, U. S. Bureau of Mines, Salt Lake City.

Fig. 6—Ignition temperature of magnesium with respect to oxygen pressure.

performed in this laboratory indicate that the ignition temperature of magnesium is lowered appreciably by contact with aluminum, nickel, and 70-30 brass. Silver and plain carbon steel did not affect the ignition temperature. The samples were prepared by drilling a hole through a piece of pure magnesium followed by reaming with a 2/0 taper pin reamer. The dissimilar metal in the form of a pin was driven in and the ends turned off thus giving a perfect contact. The values of the ignition temperatures of pure magnesium in contact with other metals are presented in Table VII (oxygen atmosphere).

#### Discussion of Results

The method developed for the determination of the ignition temperatures of magnesium and magnesium alloys is simple and reproducible. As an illustration of the accuracy of this test, ten samples of magnesium of the same lot were run in oxygen by four different individuals over a period of six months. The average ignition temperature obtained from this series of tests was:

$$623^{\circ}\text{C} \pm 0.5^{\circ}\text{C}$$

The ignition temperature of magnesium generally is lowered by the addition of alloying elements providing the melting point (liquidus) is lower than pure magnesium. Ignition of magnesium alloys may occur at temperatures either above or below the

melting point indicating that the conclusions of Carapella and Shaw<sup>8</sup> are not generally valid. The Mg-Cd system, Fig. 3, is an excellent example of this effect. The melting point of the alloy has some influence on the ignition temperature, but it is not the only factor that must be considered. This is discussed in detail in ref. 14.

One rather unusual observation was made of the magnesium and magnesium alloy samples just prior to ignition. Normally the oxide coating present is white in color. However, just an instant before ignition occurs, the oxide coating turns a dark brown or black color. Once the color change occurs, ignition follows immediately.

A correlation exists between the rates of linear oxidation and the ignition temperatures of magnesium alloys. Sufficient data to justify its presentation is available only on the Mg-Al system. Qualitatively, however, all of the alloy compositions investigated by Leontis and Rhines show the same relationship. Table VIII shows the correlation of the linear oxidation rates and the ignition temperatures of some Mg-Al alloys.

The ignition temperature of magnesium in oxygen-sulphur dioxide mixtures increases from 623°C at zero percent SO<sub>2</sub> to approximately the melting point of magnesium (650°C) at 1.7 pct SO<sub>2</sub>. From 1 to 5.8 pct SO<sub>2</sub> no further increase is observed. Qualitatively, at least, it is well known that high concentrations of SO<sub>2</sub> prevent the ignition of magnesium at temperatures considerably above the melting point. Thus, a further increase in the ignition temperature would be expected at concentrations above 5.8 pct SO<sub>2</sub> which was the maximum concentration investigated in this work.

The results obtained on the time-delay of the ignition of magnesium show that if the furnace or bath

† Extrapolated.

is maintained at some constant temperature below the ignition temperature of magnesium in oxygen, the magnesium will autoheat to the ignition temperature. The ignition temperature obtained under the conditions imposed in the time-delay experiments is identical with the value obtained in the normal ignition temperature experiments.

The approximate thickness of the oxide films present on the samples listed in Table V may be calculated from the oxidation rate data of Leontis and Rhines and an approximate value for the density of the MgO film as 0.8 g per cc. The approximate thicknesses are: Sample 1, Table V,  $5 \times 10^{-7}$  cm; Sample 2,  $1.56 \times 10^{-3}$ ; Sample 3,  $5.5 \times 10^{-3}$ . Thus the oxide film thickness changes by a factor of  $10^4$  cm yet the ignition temperature remains unchanged. This is not in agreement with the predicted results of Eyring and Zwolinsky,<sup>10</sup> see Table I.

The results obtained on the change of ignition temperature of magnesium with respect to oxygen pressure conclusively prove that the ignition reaction of magnesium is oxygen pressure dependent. The ignition temperature of magnesium increases with an increase in total oxygen pressure from 1 to 10 atm pressure. Below atmospheric pressure, the ignition temperature decreases with a minimum at about 0.4 atm, rising again at lower pressures.

The theory of ignition of metals and alloys by Eyring and Zwolinski does not account for the effect of oxygen pressure on the ignition temperature. If eq 2 is used, adsorption on the activated sites is assumed. Under increased pressures the velocity of the reaction should increase causing a decrease in the ignition temperature. This, of course, is in direct contradiction to the experimental results of the authors on ignition and of the work of Leontis and Rhines<sup>1</sup> and E. A. Gulbransen<sup>15</sup> on oxidation of magnesium.

Dissimilar metal contacts generally lower the ignition temperature of magnesium by localized diffusion and alloy formation. This would cause a small zone in which the rate of reaction is increased, accompanied by a lowering of the ignition temperature. This result has also been obtained by Willmore and Peterson.<sup>8</sup>

## Summary

A simple reproducible method of determining the ignition temperature of magnesium and magnesium alloys has been developed. This method was used to determine the ignition temperature of over 100 different magnesium alloys in oxygen at atmospheric pressure. The ignition temperature of pure magnesium was investigated in oxygen-nitrogen, oxygen-sulphur dioxide, and in oxygen from 0.166 to 10.0 atm pressure. The ignition temperature of magnesium generally is lowered by the addition of alloying elements. Ignition of magnesium alloys may occur either above or below the liquidus line. The ignition reaction of magnesium is pressure dependent, and hence any theory of ignition must satisfy this fact.

## Correction

In the March 1951 issue: *Solubility of Hydrogen in Molten Lead* by W. R. Opie and N. J. Grant. P. 245, the second equation should read:

$$\text{Log}_{10}K = \frac{-\Delta H}{4.575 T} + C$$

# Rate of Sintering of Copper Under a Dead Load

by F. N. Rhines and H. S. Cannon

The application of a static load to a copper powder compact during sintering at an elevated temperature accelerates the rate of sintering in such a way that a given load induces the same proportional increase in rate for all times of sintering. It is shown that sintering under a load is like creep under a fixed load in that the stress required to accomplish a given degree of densification is proportional to the logarithm of the sintering time.

VIRTUALLY all of the theories of sintering that have been put forward within recent years have contained the assumption that the chief driving force of the process is the surface tension resident in the exposed surfaces and internal pores of the compact, or powder mass. An externally applied load might be expected to provide a somewhat equivalent driving force for sintering. It is known that the application of a compressive load, during sintering, hastens densification, but it is by no means clear whether sintering under the influence of surface tension alone and sintering under an applied load are fundamentally similar processes. The present study was undertaken in an effort to obtain an answer to this question and with the hope that the answer may contribute to an understanding of the mechanism of sintering. It has been found that there is a close relationship between sintering and creep processes.

Copper powder compacts were sintered in hydrogen at 1000°C under dead loads of 0 to 165 psi and the progress of sintering was observed by means of density measurements. Using a commercial reduced oxide copper powder, see Table I, cylindrical compacts ½ in. x ½ in. high were made at a pressure of 12,500 psi. For sintering, these were placed in a cylindrical graphite container into which they fitted snugly. A compressive axial load was applied to the compact through a graphite rod of similar diameter, which rested upon the upper end face of the compact; iron weights, in suitable amount, were placed upon the graphite rod to provide the load. This assembly was encased in a vertical silica tube

\* Compacts prepressed at 12,500 psi. All sintering conducted at 1000°C in hydrogen.

within a resistance-type furnace capable of maintaining a substantially constant temperature within the working zone. After various predetermined times at temperature, the samples were removed from the furnace and their density was measured by conventional means. The heating-up and cooling-down times have been included in the computed sintering time, using the assumption that the sintering rate doubles for each increase of 10°C in temperature. The experimental results are presented in Table II.

Upon metallographic examination of the specimens, it was found that there was no apparent change in the shape of the pores as a result of loading, i.e. no flattening, Fig. 1. Substantial contraction away from the container walls was observed in all samples sintered with loads of 10.5 psi and less.

Fig. 1. Typical appearance of pores after 98 hr at 1000°C under a load of 70.5 psi, prepressed sample. X500.

A few experiments were made, also, using a loose powder fill in the graphite container. Again, the sintering temperature was 1000°C and the atmosphere was hydrogen. The results, shown in Table III, are similar to those for the sintering of prepressed powders except that longer times are required to attain a given density value under a given load. It is interesting that loose powder can be sintered to a density as high as 98 pct of the ideal, under a load as small as 115 psi, in as little as five days.

#### Discussion of Results

It is characteristic of sintering that the density approaches its ideal value for massive metal at a continually decreasing rate, so that complete densification is not attained within experimentally feasible times. This is seen to be true, also, when a moderate load is applied. The rate of densification is increased by loading, but within the range of loads here employed, the final approach to the ideal density is very gradual and full densification has not been attained. That sintering progresses under load in the same manner as without load is shown by Graph A, Fig. 2, wherein the "densification parameter",  $\alpha$ , is seen to be independent of time. The "densification parameter" is the ratio of the change in the percentage of porosity due to loading (at fixed time) to the percentage of porosity (at the same time) when no load has been applied:

$$\alpha = \frac{P_t - P_p}{P_t}$$

where:  $P_t$  is the percentage of porosity in an unloaded sample, and  $P_p$  is the percentage of porosity in a loaded sample sintered for the same length of time. Thus, a given load produces a constant proportional increase in densification, independent of time.

This suggests that loading, with low loads at least,

Table III—Density of Loose Powder Sintered under Load\*

| Load, Psi | Time, Hr | Density | Ideal Density, Pct |
|-----------|----------|---------|--------------------|
| 0         | 0        | 2.47    | 27.5               |
| 0         | 76       | 7.93    | 88.5               |
| 0         | 106      | 8.31    | 92.7               |
| 10        | 3        | 6.93    | 77.3               |
| 115       | 120      | 8.81    | 98.3               |

\* All sintered at 1000°C in hydrogen.

does not introduce any new mechanism into the sintering process and that the applied force is merely added to the forces (surface tension) normally present in sintering. This interpretation is fortified by the absence of any change in the shape of the pores, as a result of loading, and by the finding of radial shrinkage in samples in which the sintering rate has been accelerated materially by axial loading.

If this conclusion is justified, it becomes apparent that there is a marked similarity between sintering and creep processes, wherein gradual deformation is induced by moderate loading. It is awkward, because of the different geometrical factors involved, to compare sintering rates with creep rates, as a test of their similarity, but it is feasible to compare the two processes in another way. It is well established that the load required to produce a given deformation in steady state creep is a linear function of the logarithm of time. A similar relationship can be demonstrated for sintering, see Graph B, Fig. 2, if

Fig. 2—Densification curves.

the load required to cause densification to progress to a given value is plotted as a function of the logarithm of time. Straight line plots appear justified by the data, and it is to be noted, further, that the point for zero load (ordinary sintering) generally falls upon the line.

In considering these results it should be remembered that the range of loads tested is not large. Were much higher loads used it is to be expected that different results would be obtained, because the creep process itself changes at higher loads, steady state creep giving way to a meeting of the initial and final transient creep mechanisms. At extremely low loads, if it be imagined that the surface tension forces could be taken away, or neutralized, it should be expected again that the process would change, for there appears to be a lower limit to the force that will induce observable creep. It is suggested, therefore, that the plots of Graph B are probably the intermediate straight segments of S-curves which should terminate at infinite time at zero load and at some load lower than the extrapolated values of the present curves at zero time.

Relating sintering and creep in this way does not solve the problem of the mechanism of either process. It does suggest, however, that what is learned about the mechanism of one may be applied to the other, thereby increasing the store of knowledge that may be applied to each.

# Observations on Cleavage and Polygonization Of Molybdenum Single Crystals

by

Neng-Kuan Chen  
and  
Robert Maddin

THE {001} planes have been reported as the cleavage planes in body-centered cubic metals such as alpha-iron and tungsten.<sup>1</sup> However, in molybdenum, which is also body-centered cubic, experimental X-ray evidence indicating a similar cleavage plane still seems lacking. Tsien and Chow<sup>2</sup> observed microscopically in the extension at around 1000°C of molybdenum single crystalline wires 0.25 mm in diam that the fracture plane seemed to be

N. K. CHEN is Research Associate and R. MADDIN, Junior Member AIME, is Assistant Professor, The Johns Hopkins University, Baltimore.

Discussion on this paper, TP 3084E, may be sent, 2 copies, to AIME by Dec. 1, 1951. Manuscript, Feb. 12, 1951. Detroit Meeting, October 1951.

parallel to the operative slip plane, which appeared to be {110} at that temperature. Zapffe<sup>3</sup> pointed out from fractographic study of polycrystalline molybdenum that "although the transgranular pattern is characteristically non-crystallographic, patterns occasionally reveal {100} cleavage." This has been generally assumed to be the case at ordinary temperatures.

In the present experiments, a single crystal of Fansteel molybdenum,  $\frac{1}{8}$  in. diam x 2 in. long, prepared by the methods described by Chen, Maddin, and Pond<sup>4</sup> was fractured at room temperature by bending. The fracture surface appeared to be quite similar to the cleavage surface of zinc and was crystallographic. A back-reflection Laue photogram was made using 35 kv copper white radiation; the X-ray

Fig. 1—Laue back-reflection photogram. X-ray beam perpendicular to (100) cleavage face of a molybdenum single crystal.

Fig. 2—Slip lines in a molybdenum single crystal at about 2400°C. X800.

Fig. 3 (left)—Laue back-reflection photograph of a single crystal of molybdenum bent at about 2400°C.

beam was perpendicular to the cleavage surface. From Fig. 1 it can be concluded that the (100) plane is the plane of cleavage.

An interesting phenomenon apart from the cleavage described above was the polygonization of a single crystal of molybdenum after being bent at around 2400°C. The specimen was  $\frac{1}{8}$  in. in diam x 6 in. long containing a single crystal in the center section about  $1\frac{1}{4}$  in. long. It was polished electrolytically and then reheated in the modified Andrade furnace<sup>4</sup> to a temperature of about 2400°C in 30 min. The specimen expanded freely up to a temperature of about 2200°C as measured by a dilatometer. At a temperature of between 2300° and 2400°C, the expansion was inhibited in some manner so as to cause a sudden sharp dip in the dilatometer reading. After examination at room temperature, a sharp bend through an angle of 15° was noted in the single crystal.

Slip lines observed at room temperature were broad and well-marked and appeared to be very branched, Fig. 2. X-ray photographs taken on three sides of the bent section revealed the orientation of the original crystal. However, the Laue spots were elongated and divided into small individual areas as shown in Figs. 3 and 4. The break-up of Laue spots in deformed crystals after annealing has been observed in aluminum, sodium, zinc and silicon ferrite. It has been termed polygonization by Orowan and Cahn.<sup>5</sup> They reasoned that an elastically bent lattice could be transformed into strain-free polygons by annealing. Recent work by Dunn and Daniels<sup>6</sup> on silicon-iron crystals also confirmed this phenomenon. Thus the present observation on the polygonization of a bent single crystal of molybdenum at high temperature is comparable to the behavior of other metals.

A stereographic plot of the Laue streaks in Fig. 3 is shown in Fig. 5. It should be noted that the rotation of the crystallites is about a [112] axis, which is in the slip plane (110) and 90° from the slip direction [111]. This checks with the microscopic observations of slip and also confirms the general type of crystal rotation in the plastic deformation of single crystals.

Fig. 5—Stereographic projection of Laue streaks (Fig. 3) showing crystal rotation.

Open representations show the beam perpendicular to the plot at center and stress axis coincides with horizontal diameter. Closed representations show X-ray beam and stress axis perpendicular to plot at center. SD, SP, and SA refer to slip direction, slip plane, and stress axis, respectively.

# Secondary Recrystallization in Copper Wire

by Guido Bassi

IT is known<sup>1-3</sup> that secondary recrystallization occurs in copper sheet with at least 90 pct reduction after annealing at high temperatures, 700° to 1000°C. Turkalo and Turnbull<sup>4</sup> have found recently that secondary recrystallization might occur even after annealing at such low temperatures as 500°C for a high purity, coarse-grained copper sheet. It will be shown in the following that in an electrolytic tough pitch copper wire, with a high degree of deformation, secondary recrystallization might occur at even lower temperatures.

A hot-rolled rod of 9.5 mm diam (temperature at which rolling commenced was 850°C) was drawn in continuous drawing machines to 0.4 mm, corresponding to a cross-section reduction of 99.8 pct. The texture in the center of the wire (the sample for X-ray analysis was etched to 0.15 mm diam) is a mixture of the [111] and the [100] direction, as

can be seen from Fig. 1. This is in accordance with the result of Schmid and Wassermann.<sup>5</sup> After a few minutes annealing of the wire at 200°C, there is a noticeable recrystallization of the structure with a preferred orientation in the [100] direction at the expense of the [111] deformation texture, as Figs. 2 and 3 show. Farnham and O'Neill<sup>6</sup> reported a similar result. The final recrystallized structure shows mainly the [100] orientation. There is however a small amount of [111] and random orientations.

If the wire is annealed at 400°C, the recrystallized structure first shows a [100] texture, Fig. 4, but as the annealing time is increased the fine-grained structure transforms into coarse grains, Fig. 5, giving a new preferred orientation, Fig. 6. The calculations show this to correspond to the [112] direction. Even if the annealing that gives the primary recrystallization is carried out for six weeks at 200°C, the same secondary recrystallization texture is obtained if the annealing is continued at 400°C. Schmid and Wassermann<sup>7</sup> found the [112] texture, but only after annealing at 1000°C or higher.

The appearance of a secondary recrystallized

structure aligned in the [112] direction at such a low temperature as 400°C is due partly to the very high degree of deformation of the wire. The following two experiments show that the deformation is not the only factor of importance.

1—If electrolytic tough pitch copper is extruded at 925°C into a rod of 19 mm diam (average grain size, 0.05 mm) and drawn to 0.5 mm, corresponding to a reduction of 99.9 pct, then secondary recrystallization is found only after annealing at 800°C or higher. The interference spots on the X-ray film are not so sharp as in Fig. 6.

2—If the earlier mentioned hot-rolled rod of 9.5 mm is annealed 1 hr at 1050°C before being drawn to 0.4 mm, then the final recrystallized structure has a random orientation after annealing at 400°C. The grains are not too coarse, Fig. 7.

The deformation textures from these two experiments were similar to that of Fig. 1 and both showed a primary recrystallization structure with the [100] texture. The observations indicate that the occurrence of secondary recrystallization at 400°C, and the sharpness of the resulting texture are affected by other factors of the previous treatment, in addition to the final deformation. This may be the second last deformation and annealing. After the second last annealing there are areas or grains that are given a higher energy than the average in the last deformation. After the primary recrystallization these high energy grains have become grains with a lower energy than the average. As the annealing goes on, these grains grow at the expense of the neighboring grains with a higher energy. This theory regards secondary recrystallization merely as a coarsening of the primary recrystallized structure.

The [112] texture can be obtained at still lower temperatures. If the hard-drawn wire of 0.4 mm first is annealed 6 hr at 200°C, giving the [100] texture, and then drawn to 0.38 mm, corresponding to a reduction of 9.5 pct, secondary recrystallization with the [112] texture occurs even at 200°C, Fig. 8. Wilson and Kronberg<sup>3</sup> showed a similar result with coarse grains when giving a light reduction to a copper sheet with the cube texture. They regarded this not as secondary recrystallization but as primary recrystallization after critical deformation. It has not been found before however that primary recrystallization can occur after such a low reduction as 9.5 pct and annealing at 200°C. It seems more logical to call it secondary recrystallization.

# A Thermodynamic Study of the Reaction $\text{CaS} + \text{H}_2\text{O} \rightleftharpoons \text{CaO} + \text{H}_2\text{S}$ And the Desulphurization of Liquid Metals with Lime

by Terkel Rosenqvist

THE desulphurization of molten iron and steel is a very complicated process. One way to arrive at a better understanding of this process is to break it down into several simpler chemical processes that can be studied individually in the laboratory. For a study of the different factors that influence the equilibrium distribution of sulphur between liquid metals and slags, several simpler equilibria may be investigated. One very important subject is the determination of the escaping tendency of sulphur in the liquid metal and its dependency on temperature and composition of the melt. Several papers in this field have recently been published.<sup>1, 2</sup>

Another subject is the study of the sulphur capacity of the slag. A molten slag is indeed complex, and even if sulphur distribution data for a large variety of molten slags may give empirical data about their desulphurizing power, the importance of the individual components is still not quite clear. It is accepted generally that lime is the most important desulphurizing component in the slag. The present investigation has as its purpose to study the desulphurizing power of lime in its standard state, and to provide a basis for thermodynamic calculations of the desulphurizing power of various lime-containing slags.

The standard state of lime at steelmaking temperatures is solid calcium oxide,  $\text{CaO}$ . It can react with sulphur to form solid calcium sulphide,  $\text{CaS}$ . The relative stability of calcium oxide and calcium sulphide is expressed by the free energy of the reaction:

The existing free energy data for this reaction, listed by Kelley<sup>3</sup> and Osborn,<sup>4</sup> are uncertain to about 10 kcal and are of limited value for a calculation of equilibrium constants.

Under the conditions prevailing in a melting furnace, the sulphur pressure may be expressed conveniently by the ratio  $\text{H}_2\text{S}/\text{H}_2$  and the oxygen pressure by the ratio  $\text{H}_2\text{O}/\text{H}_2$  (or  $\text{CO}_2/\text{CO}$ ). The desulphurizing power of calcium oxide may, therefore, be studied by the reaction  $\text{CaO} + \text{H}_2\text{S} = \text{CaS} + \text{H}_2\text{O}$ .

A study of this reaction may be complicated by certain side reactions: Water vapor and hydrogen sulphide may react to form sulphur dioxide, and calcium sulphide may be oxidized to calcium sulphate. A thermodynamic calculation shows that these side reactions will be suppressed to insignificance if the equilibrium is studied in the presence of an excess of hydrogen.

The apparatus used is shown in Fig. 1. About 10 g calcium oxide and 20 g calcium sulphide (laboratory

qualities) were intimately mixed, and some water was added to make a thick paste. The paste was put into a thimble of zirconium silicate, which was placed within the constant temperature zone of a furnace, and capillary refractory tubes were attached in both ends. After the mixture had been heated in dry hydrogen at  $1000^\circ\text{C}$  for several hours all  $\text{Ca}(\text{OH})_2$  and  $\text{CaCO}_3$  had decomposed and  $\text{CaSO}_4$  was reduced, so only  $\text{CaO}$  and  $\text{CaS}$  remained in the thimble forming a porous plug.

The mixture was examined by X-ray diffraction after the initial reduction in dry hydrogen as well as after the subsequent experimental runs up to  $1425^\circ\text{C}$ . It was shown that crystalline calcium oxide and calcium sulphide were always present together in about equal amounts. The unit cell edges were found to be 4.80 Å for  $\text{CaO}$  and 5.68 Å for  $\text{CaS}$  in good agreement with existing literature values.<sup>5</sup> This shows that the mutual solid solubility is very small, and that the compounds are present in their standard states.

Purified hydrogen was passed through water saturators kept at constant temperature in a thermostat bath. The amount of water vapor saturation was checked by means of a dew point method, not shown on Fig. 1. The gas mixture was passed through the capillary inlet into the furnace, where it was sifted through the porous plug of calcium oxide and calcium sulphide.

The hydrogen sulphide present in the outgoing gas was absorbed in a zinc acetate solution and the hydrogen was collected over water. When one liter of hydrogen had been collected, the amount of hydrogen sulphide was determined by iodometric titration. As one molecule of  $\text{H}_2\text{O}$  is used for the formation of each molecule of  $\text{H}_2\text{S}$ , the equilibrium

ratio  $\text{H}_2\text{S}/\text{H}_2\text{O}$  would be  $\frac{(\text{H}_2\text{S})}{(\text{H}_2\text{O}) - (\text{H}_2\text{S})}$ , where

$(\text{H}_2\text{O})$  is the molar concentration in the ingoing gas, and  $(\text{H}_2\text{S})$  the molar concentration in the outgoing gas. In the present work  $(\text{H}_2\text{S})$  was always very small compared to  $(\text{H}_2\text{O})$ .

In order for the observed  $\text{H}_2\text{S}/\text{H}_2\text{O}$  ratio to represent the true equilibrium ratio the gas flow has to be: 1—Sufficiently slow to give a complete establishment of equilibrium, and 2—sufficiently fast to counteract thermal diffusion. Incomplete reaction would give a value decreasing with increasing flow rate, and thermal diffusion would give a value increasing with decreasing flow rate. When inlet and outlet tubes of about 2 sq mm cross-section were used, the observed gas ratio was independent of the flow rate between 15 and 125 cc per min, Fig. 2. In this range, therefore, the observed gas ratio represents true equilibrium.\* For the rest of the in-

\* This was not found to be true when the inlet and outlet tubes were of about 20 sq mm cross-section. In that case thermal diffusion was significant at a flow rate of 125 cc per min.

T. ROSENQVIST, Junior Member AIME, is with the Institute for the Study of Metals, University of Chicago, Chicago.

Discussion on this paper, TP 3086C, may be sent, 2 copies, to AIME by Sept. 1, 1951. Manuscript, Feb. 15, 1951. St. Louis Meeting, February 1951.

Fig. 1—Apparatus for study of the equilibrium  $\text{CaS} + \text{H}_2\text{O} = \text{CaO} + \text{H}_2\text{S}$ .

vestigation the flow rate was kept between 50 and 80 cc per min.

Fig. 3 shows that when the  $\text{H}_2\text{O}/\text{H}_2$  ratio was varied over a wide range the  $\text{H}_2\text{S}/\text{H}_2$  ratio varied proportionally. This shows that the hydrogen sulphide in the outgoing gas actually is formed by the proposed reaction.

A thermocouple was inserted in the reaction mixture and the measurements were made from  $750^\circ$  to  $1425^\circ\text{C}$ . At the highest temperature a slight slagging was observed on the contact between the thermocouple and the reaction mixture, but without affecting the bulk of the mixture.

### Experimental Results

The experimental results listed in Table 1 represent the average of from two to five single analyses for each temperature. In Fig. 4 the logarithm of the gas ratio is plotted vs.  $1/T$ .

For the reaction  $\text{CaS}(s) + \text{H}_2\text{O}(g) = \text{CaO}(s) + \text{H}_2\text{S}(g)$ , the enthalpy is:

$$\Delta H = 15,650 \text{ cal}$$

and Gibbs free energy:

$$\Delta F^\circ = 15,650 - 0.87 \cdot T \text{ cal}$$

These values apply to temperatures between  $750^\circ$

Fig. 2—Effect of flow rate on the ratio  $\text{H}_2\text{S}/\text{H}_2\text{O}$ .

The dotted lines indicate the expected effects of thermal diffusion at low flow rates, and incomplete reaction at high flow rates.

and  $1425^\circ\text{C}$ , but as  $\Delta C_p$  of the reaction is small, they are assumed valid up to steelmaking temperatures of about  $1600^\circ\text{C}$ .

In this temperature range the free energy is about 3 kcal higher than that calculated from Osborn's free energy survey.\*

### Desulphurization of Liquid Copper

The escaping tendency of sulphur dissolved in a molten metal may be expressed conveniently by the equilibrium  $\text{H}_2\text{S}/\text{H}_2$  ratio which can be determined from the reaction:  $\text{S}(\text{dissolved}) + \text{H}_2 = \text{H}_2\text{S}$ . If this reaction is combined with the reaction  $\text{CaO} + \text{H}_2\text{S} = \text{CaS} + \text{H}_2\text{O}$ , one obtains:

As for low concentrations, the sulphur activity is closely proportional to the sulphur concentration, the sulphur content of a melt in equilibrium with solid calcium oxide and solid calcium sulphide will be closely proportional to the ratio  $\text{H}_2\text{O}/\text{H}_2$  in the atmosphere.

In order to see if this relationship actually holds, the desulphurization of liquid copper with lime was investigated. It was hoped in that way to obtain

Fig. 3—Correlation between  $\text{H}_2\text{O}/\text{H}_2$  and  $\text{H}_2\text{S}/\text{H}_2$  ratio.

some information that might be useful for an understanding of the factors affecting the desulphurization of iron and steel. The principles behind the reaction would be the same for copper as for iron.

Hydrogen, saturated with water vapor at various temperatures, was bubbled through a copper melt in contact with solid CaO and solid CaS until equilibrium between the gas, the liquid, and the solid phases was established, Fig. 5. All runs were made at 1200°C. Most of the runs were carried out with about 50 g copper of 1.5 to 2.5 pct initial sulphur content and 3 to 5 g calcium oxide. Calcium sulphide then was formed during the reaction. A few preliminary runs, No. 12 and No. 16 (Table II), were made with a smaller amount of pure copper in contact with a larger amount of CaO and CaS. These runs gave results in agreement with the rest of the work. In all cases crucibles of zirconium silicate were used.

The amount of oxygen introduced in the copper melt by this procedure can be calculated from the recent investigation by Girardi and Siebert.<sup>6</sup> At 1200°C the oxygen concentration expressed in weight percentage will about equal  $H_2O/H_2 \cdot 10^{-4}$ . As in the present work the ratio  $H_2O/H_2$  was maintained between 1/20 and 1/2, the oxygen content will be of the order of  $10^{-5}$  pct. It is assumed that this will have no significant effect on the activity coefficient of sulphur in the melt.

Samples were drawn from the liquid copper by means of an arrangement similar to that used by Hatch and Chipman.<sup>7</sup> In order to prevent air from leaking into the apparatus when the sampler was inserted or removed, the tube was flushed with nitrogen during these operations, Fig. 5. The entire sample, 2 to 5 g, was dissolved in nitric acid and bromine and, after removal of the copper by electrolysis, sulphur was determined by precipitation as  $BaSO_4$ .

In some cases X-ray diffraction diagrams were taken of the crust of solids that remained in the crucible after the copper had been poured out. Invariably the lines of CaO and CaS were found proving that these compounds were present in their standard state.

In Fig. 6 the approach to equilibrium is studied as a function of time for a sequence of different gas compositions. Even if the scattering of the points is large, it is evident that there is no systematic trend with time after 5 hr of constant gas composition. Furthermore, Fig. 6 shows that the sulphur content is established equally well from the high as from the low side. It is therefore concluded that equilibrium values are established in about 5 hr, and in Table II are listed the results of various runs based on samples drawn after 5 to 29 hr of constant gas composition. The values were obtained about equally by approach from the high as from the low side.

During the reaction a small amount of hydrogen sulphide is formed, corresponding to the equilibrium  $H_2S/H_2$  ratio. This causes a removal of sulphur from the copper melt, a loss which has to be replenished by transfer of sulphur from the "slag." Equilibrium can only be expected when a significant amount of CaS remains, and when the rate of transfer between the slag and the metal is higher than the rate at which sulphur is removed as hydrogen sulphide. The general agreement between the values obtained by approach from both sides indicates that this is the case. Furthermore, the rate of sulphur removal

Fig. 4—Log  $H_2S/H_2O$  against  $1/T$ .

can be estimated from the  $H_2S/H_2$  ratio and the gas flow and, in the present case, is between 0.002 and 0.02 g per hr. This appears to be considerably less than the rate of sulphur transfer between the copper melt and the "slag" as estimated from the rate at which equilibrium is approached, Fig. 6.

Nevertheless, a certain instability is introduced due to the continuous removal of sulphur as hydrogen sulphide. This instability may be one of the reasons for the scattering of points in Figs. 6 and 7.

Fig. 7 shows that for less than 1 pct S the sulphur content of the copper melt is closely proportional to the ratio  $H_2O/H_2$ . The scale on the right hand side of Fig. 7 gives the corresponding  $H_2S/H_2$  ratio calculated from the data given in Table I.

The equilibrium  $S(\text{in Cu}) + H_2 = H_2S$  was investigated recently by Sudo.<sup>8</sup> For a temperature of 1200°C his data give an equilibrium ratio

$$\frac{H_2S}{H_2 \cdot \%S} \text{ equal to about } 4.5 \cdot 10^{-3}, \text{ valid for sulphur}$$

contents up to 0.87 pct. As seen from Fig. 7 this value is in very good agreement with the results of the present investigation.

For molten copper in equilibrium with molten cuprous sulphide Schuhmann and Moles<sup>9</sup> have found the  $H_2S/H_2$  ratio equal to  $4.2 \cdot 10^{-3}$  at 1200°C. According to Fig. 7 this should correspond to a maximum solubility of about 1 pct S in liquid copper. This is about half the solubility that is generally

accepted.<sup>10</sup> In order to verify this finding, extended work by this and other methods have to be made.

#### Application to Blast Furnace Desulphurization

In a recent careful study, Hatch and Chipman<sup>7</sup> determined equilibrium values for the distribution of sulphur between carbon-saturated iron and various blast furnace slags in an atmosphere of pure CO. These authors were unable, however, to correlate their results with any theoretically calculated distribution coefficient. This may be due partly to insufficient knowledge about the activities of various constituents in the slag.

In this section Hatch and Chipman's data will be used, in connection with the data obtained in the present investigation, to calculate activity data for the slag.

If the reaction  $\text{CaS} + \text{H}_2\text{O} = \text{CaO} + \text{H}_2\text{S}$  is combined with the water gas reaction  $\text{H}_2\text{O} + \text{C} = \text{H}_2 + \text{CO}$  to give:

Fig. 6—Effect of time on the sulphur content of the copper melt.

The horizontal levels given for each gas composition correspond to the sulphur values given by the curve on Fig. 7.

then

$$\Delta F^\circ = 17,210 - 34.09 \cdot T \text{ cal}$$

is obtained. The escaping tendency of sulphur in liquid iron is given by Sherman, Elvander, and Chipman:<sup>1</sup>

$$\Delta F^\circ = 9,840 + 6.54 \cdot T \text{ cal}$$

The reference state for sulphur here is chosen to be an ideal 1 pct solution of sulphur in pure iron. For the reaction:

therefore is obtained:

$$\Delta F^\circ = 27,050 - 27.55 \cdot T \text{ cal}$$

or at a temperature of 1500°C:

$$K = \frac{a_{\text{CaS}} \cdot p_{\text{CO}}}{a_{\text{CaO}} [\text{S}] \cdot f_{\text{S}} \cdot a_{\text{C}}} = 490$$

Under the conditions studied by Hatch and Chipman  $p_{\text{CO}}$  and  $a_{\text{C}}$  were both unity. For iron saturated with carbon at 1500°C, Morris and Buehl<sup>2</sup> found the activity coefficient  $f_{\text{S}}$  equal to about 5.8.

This gives for a system in equilibrium with graphite and a CO atmosphere:

$$\frac{a_{\text{CaS}}}{a_{\text{CaO}}} = 2842 \cdot [\text{S}]$$

The activities  $a_{\text{CaS}}$  and  $a_{\text{CaO}}$  are referred to the pure solids as standard state, and  $[\text{S}]$  is the sulphur content of the iron melt in weight percentage.

The activity of calcium oxide in a calcium silicate melt can be approximately derived from the free energy diagram of the system  $\text{CaO-SiO}_2$  given by Darken.<sup>11</sup> For a melt with the ratio  $\text{CaO/SiO}_2 = 1$ ,  $a_{\text{CaO}} \approx 0.010$  and for a melt with  $\text{CaO/SiO}_2 = 1.5$ ,  $a_{\text{CaO}} \approx 0.025$ . In Table III these values are combined with sulphur distribution data obtained by Hatch and Chipman and values for  $a_{\text{CaS}}$  are calculated.

In Fig. 8 the activity of CaS is plotted vs. the sulphur content of the slag, (S). For both types of slag the activity may be represented adequately by one single curve. The activity seems to reach unity at about 10 pct S. This value agrees rather well with McCaffery and Oesterle's<sup>12</sup> experimental values

Table II. Desulphurization of Molten Copper

| Sample Number | H <sub>2</sub> O/H <sub>2</sub> | Wt Pct S | Sample Number | H <sub>2</sub> O/H <sub>2</sub> | Wt Pct S |

| 37            | 0.059                           | 0.09     | 87            | 0.253                           | 0.30     |
|               |                                 |          | 88            | 0.260                           | 0.45     |

Fig. 7—Sulphur in molten copper as a function of the ratio  $H_2O/H_2$ .

The right hand scale gives the corresponding  $H_2S/H_2$  values.

for the solubility of CaS in various blast furnace slags. These authors found the CaS solubility at  $1500^\circ\text{C}$  to vary from about 8 pct S for acid slags to about 11 pct for the more basic slags. Glaser<sup>13</sup> found the solubility of CaS in a pure  $\text{CaSiO}_3$  melt corresponding to 5.5 pct S at  $1500^\circ\text{C}$ . Furthermore Glaser showed that at a somewhat higher sulphur content and temperature a region of liquid immiscibility occurred. This means that  $a_{\text{CaS}}$  would be expected to show a pronounced positive deviation from ideality. This is confirmed by Fig. 8.

The agreement between the activity data given in Fig. 8 and the activities to be expected from solubility data actually confirms the values for  $a_{\text{CaO}}$  which with considerable uncertainty were derived from Darken's free energy diagram.

If the slag had contained an excess of solid CaS,  $a_{\text{CaS}}$  would be unity and at  $1500^\circ\text{C}$ :

$$a_{\text{CaO}} = \frac{3.52}{[\text{S}]} \cdot 10^{-4}$$

An experimental determination of the sulphur content of the iron melt under these conditions may give us a possible way to determine activity values for CaO in slags of various compositions and basicities.

The general conclusion of this investigation is that the activity of sulphur in a molten metal in equilibrium with a slag will be proportional to the atomic oxygen fugacity in the system, expressed by

Fig. 8—Activity of CaS in blast furnace slags.

the ratio  $H_2O/H_2$ ,  $\text{CO}_2/\text{CO}$ , or  $\text{CO}/a_{\text{O}}$ , and proportional to the ratio  $a_{\text{CaS}}/a_{\text{CaO}}$  in the slag. The activities  $a_{\text{CaO}}$  and  $a_{\text{CaS}}$  are exactly defined quantities and do not correspond to any assumed picture of "free lime" or "sulphur combined with calcium."

Most probably liquid slags are highly ionized and, for the lack of any dissociation constants, activities can be defined for the sulphur and oxygen ions, so that:

$$\frac{a_{\text{CaS}}}{a_{\text{CaO}}} = \frac{a_{\text{S}^{2-}}}{a_{\text{O}^{2-}}}$$

If the ratio between the activity  $a_{\text{S}^{2-}}$  and percentage of sulphur in the slag (S) is called  $\gamma_{\text{S}^{2-}}$ , it will be seen that the amount of sulphur a given slag will absorb under a given oxygen and sulphur fugacity will be proportional to  $a_{\text{O}^{2-}}/\gamma_{\text{S}^{2-}}$ .

This quantity can be called the sulphur-capacity of the slag. It is a fundamental, intrinsic property of the slag, the detailed knowledge of which would be of considerable importance. This quantity may be determined experimentally by passing a controlled mixture of hydrogen, hydrogen sulphide, and water vapor through the molten slag and determining the equilibrium sulphur content (S). The relation then will be:

$$\frac{a_{\text{O}^{2-}}}{\gamma_{\text{S}^{2-}}} = K \cdot \frac{H_2O}{H_2S} (S)$$

K is equal to the equilibrium constant for the reaction  $\text{CaS} + \text{H}_2\text{O} = \text{CaO} + \text{H}_2\text{S}$ , as given in Table I and Fig. 4.

A research program along these lines is planned.

### Summary

The desulphurizing power of calcium oxide in its standard state has been investigated.

1—The reaction  $\text{CaS} (s) + \text{H}_2\text{O} (g) = \text{CaO} (s) + \text{H}_2\text{S} (g)$  has been studied from  $750^\circ$  to  $1425^\circ\text{C}$ . The Gibbs free energy of the reaction can be expressed as follows:

$$\Delta F^\circ = 15,650 - 0.87 \cdot T.$$

See Table I and Fig. 4.

2—The desulphurization of liquid copper with calcium oxide has been studied at  $1200^\circ\text{C}$ . It is found that the sulphur content in the copper is closely proportional to the  $H_2O/H_2$  ratio in the atmosphere, as would be expected in accordance with the equation:

The results indicate a maximum solubility of sulphur in liquid copper at  $1200^\circ\text{C}$  of about 1 wt pct, Table II and Fig. 7.

3—The obtained data for the desulphurizing power of calcium oxide have been combined with blast furnace desulphurization data, obtained by

Hatch and Chipman,<sup>7</sup> and with calcium oxide activity data obtained from Darken's free energy diagram of the system CaO-SiO<sub>2</sub>.<sup>11</sup> Values for  $a_{\text{CaS}}$  are calculated for slags of various basicities and sulphur contents, Table III and Fig. 8.

With emphasis on the ionic theory for liquid slags the expression  $\frac{a_{\text{CaO}} \cdot S}{a_{\text{CaS}}} = \frac{a_{\text{O}^{2-}}}{\gamma_{\text{S}^{2-}}}$  is suggested as a measure for the sulphur capacity of the slag.

### Acknowledgments

The first part of this work was carried out with the help and assistance of E. M. Cox, the second part with assistance of B. L. Dunicz. Their help is thankfully acknowledged. The copper-sulphur samples were analyzed by Miss M. C. Bachelder, Mrs. E. W. Nobile and A. A. Roman; thanks are due to them.

### Technical Note

## Effect of Hardness on Temper Brittleness

by D. C. Buffum and L. D. Jaffe

QUANTITATIVE measurements of the temper brittleness of steel are made by comparing the difference between embrittled and unembrittled specimens in the temperature of transition from ductile to brittle fracture. Since hardness affects the transition temperature, a study of the combined effects of hardness and temper brittleness appeared desirable.

In this investigation a commercial SAE 3140 steel, which has been reported on previously in temper brittleness studies,<sup>\*</sup> was used. Blanks from this steel were austenitized for 1 hr at 900°C and water quenched. The blanks were then divided into six groups and further heat treated as follows: Group 1—tempered at 675°C for 4 hr and water quenched; Groups 2, 3, 4, and 5—tempered at 675°, 650°, 625°, and 600°C respectively for 1 hr and water quenched; and Group 6—tempered at 500°C for ½ hr and water quenched.

Each of these groups was divided into two parts; one part was tested without further heat treatment, and the other was embrittled for 48 hr at 500°C and water quenched. Tempering treatments between 500° and 600°C were avoided because of the rapid embrittlement occurring in that range for this steel.

The heat-treated blanks were machined into standard V-notched Charpy bars. Each group was tested over a range of temperatures on a 217 ft-lb Charpy machine.

The energies necessary to fracture the bars and the percentage fibrous fracture of each bar were recorded. The transition temperatures were obtained from a plot of the percentage fibrous fracture as a function of testing temperature. They were taken as the lowest point on these curves at which the fracture was 100 pct fibrous. The transition temperatures for both embrittled and unembrittled

Fig. 1—Transition temperature as a function of hardness. Numbers indicate heat treatment groups.

specimens are presented in Fig. 1 as function of the hardness. It will be noticed in this figure that the point for the unembrittled condition at 21 Rockwell C is out of line. These specimens were tempered for 4 hr at 675°C and this point indicated that under isothermal conditions at this temperature, as is well known, embrittlement may develop fast enough to more than offset the effects of softening.

From this data, it was concluded that the difference between transition temperatures for the embrittled and unembrittled conditions at any given hardness, within the range of Rockwell C 24½ to 32½, is constant.

It is also concluded that, within the hardness range studied, the transition temperatures for embrittled and unembrittled specimens rise in a parallel fashion with an increase in hardness.

The authors wish to acknowledge the assistance of Frank Carr in this work.

## An Experimental Survey of Deformation and Annealing Processes in Zinc

by D. C. Jillson

### DISCUSSION, B. Averbach presiding

**J. R. Lane** (*Metals Research Laboratory, Washington*)—A new type of deformation called “kinking” has recently been described. Is there any relation between the “rumpling” described in this paper and “kinking?”

**D. C. Jillson** (author's reply)—Both are manifestations of bending about [210] axis. The difference is one of degree.

**W. C. Ellis** (*Bell Telephone Laboratories, New York*)—Some observations of deformation in zinc recorded in this paper may be applicable generally to flow in metals. One of these, deformation in torsion without evidence of slip or twinning in the early stages and with startling ease, when the twist is about the hexagonal axis, adds another method of flow to the presently increasing list of mechanisms. This illustrates again that a crystal will utilize any realizable process to flow and relieve stress. The process is not necessarily classical directional slip—in this case, it is rotational slip. The question naturally occurs: Will face-centered cubic metals stressed by twisting about an octahedral axis flow in a similar manner by rotation on an octahedral plane? I would like to ask Dr. Jillson if he has

made any experiments or knows of any experiments of this type on face-centered cubic metals? Face-centered cubic metals possibly would behave differently from zinc, since, for one thing, the stacking sequence is different for the two structures. The results of such experiments, however, would be instructive in providing more information about deformation processes.

**D. C. Jillson**—Dr. Roy E. Swift, working in the Hammond Laboratory at Yale, performed a twist test on a single crystal of brass. The work has not been published, and I do not know the crystallographic direction of the axis of the specimen used.

**Lo-ching Chang** (*Columbia University, New York*)—Observations similar to Figs. 1 and 2 of the paper were obtained by us during the bending and unbending of an orthorhombic Au-Cd alloy.<sup>51</sup> This orthorhombic alloy is the product of diffusionless transformation from a single crystal of  $\beta$  Au-Cd alloy (CsCl structure) containing 47.5 atomic pct Cd on cooling to about 60°C.<sup>52</sup> Referring to the effects of annealing, has the author tried any long time high temperature anneal, such as 150 to 200 hr at 400°C?

**D. C. Jillson**—No.

**C. Crussard** (*Ecole des Mines, Paris, France*)—I

Fig. 16—Grain at the surface of a uranium polycrystal compressed 2 pct, showing twinning, slip, and kink bands. The kink bands are the broad markings. X100.

Area reduced approximately 66 pct for reproduction.

would like to mention a few observations on the twinning and detwinning of a zinc crystal, which I made<sup>53</sup> and which are in agreement on many points with those of Dr. Jillson. The crystal was made by recrystallization, which is rather easy with impure zinc, but becomes more difficult, the purer the metal; as I have explained elsewhere,<sup>55</sup> with the 99.99 pct Zn used, it was very difficult to prepare single crystals by this method; only three were obtained.

One crystal had an orientation with the basal plane parallel to the axis of the specimen. This made it unsuitable for elongation; but it could easily twin by torsion. The twin was studied by torsion under the microscope. As observed by Dr. Jillson, a rather strong torque had to be applied to make the twin start, with a click; after which, the twin grew under a very small torque, without hardening. Reversal of the stress caused progressive detwinning, under a small torque, until a faint line only was visible. But this last trace did not disappear; under a new reversal of stress it could grow again under a small torque, as the first time. The operation could be repeated.

When a fine line was left, it could disappear (with a click) under a strong (reverse) torque, of the same order as that necessary to initiate the twin. After complete disappearance of the twin, when I tried to produce a new twin, it started in another place. Thus it seems that the "nucleus" of a twin is hard to produce; but once produced, it has an appreciable stability.

The "rumpling" shown by the author is very interesting. It can be interpreted as a polygonization during deformation. The latter has been observed in my laboratory<sup>54</sup> in all types of deformation in aluminum; it is very strongly developed during creep. In other words, dislocations show two competitive trends: To cluster in walls, or to trigger "avalanches," if they have enough kinetic energy. The latter factor is the key to the whole problem.

**D. C. Jillson**—It is difficult to grow strain-anneal single crystals of high-purity zinc, as reported by Mathewson and Phillips.<sup>56</sup> We found at that time that a critical content and, perhaps, dispersion of iron was helpful.

Regarding detwinning, it seems likely that the conditions in Professor Crussard's torsion specimen were not so simple as those in some of our specimens and that his inability to detwin them completely without an increase in stress may have been due to this. We were frequently unable to detwin completely in specimens where the deformation was more extensive.

**R. W. Cahn** (Ministry of Supply, Atomic Energy Research Establishment, Harwell, Berks, England)—Dr. Jillson's observations on the widespread prevalence of glide-plane bending in zinc will, I am sure, assist considerably towards a complete understanding of the plastic behavior of metals. What is particularly interesting is the apparently general tendency for uniform curvature in a lattice to turn into a segmented or "polygonized" curvature. This is brought out by the X-ray photographs in the paper which show that a

segmented curvature exists in a zinc crystal immediately after bending, albeit on a very fine scale. This observation is also in line with Ramsey's observations<sup>58</sup> on the cell structure of polycrystalline zinc extended at room temperature. I have found what is almost certainly an instance of the same phenomenon both in stretched and in compressed polycrystalline uranium, Fig. 16. Here there are pairs of bend planes, of opposite sense, approximately normal to the slip direction, just as in the cases illustrated by Jillson: These pairs constitute "kink bands."

It seems to me that in all these cases, the basic phenomenon is that of the single bend plane. A kinked zinc crystal contains numerous such planes of both senses, combined with sharp continuous curvature, while a bent crystal, according to Dr. Jillson, contains a very large number of feeble bend planes of the same sense. The so-called deformation bands in aluminum, studied at Yale University, by Honeycombe,<sup>57</sup> and by myself among others, are probably constituted by pairs of bend planes, as recently suggested by Mathewson.<sup>58</sup> Fig. 17 is a photograph of such a band in aluminum. It was generally found, as here, that one side of the band was more sharply curved than the other. The occurrence of such bands formed in tension, and kink bands in zinc formed by compression, are not consistent with Dr. Jillson's picture suggested at the end of his paper. He proposes that bands are formed and disappear again periodically, each such cycle being associated with a sort of slip quantum. In the cases just cited, however, the bend planes, once created, form a permanent barrier in the lattice: They become progressively sharper, each acting as a sieve in retaining dislocations of one sign. The effect of annealing seems to be to sharpen the curvature. This may happen by a segmentation of an apparently continuous curvature, as in Fig. 18, which was made from a deformation band in an aluminum crystal annealed after extension, repolished after annealing, and then slightly stretched again; or it may happen by a coalescence of segments already existing, as would appear to be the case when a bent zinc crystal is annealed. The motion of dislocations involved in such processes can be very considerable and may be evidenced by a visible change in the shape of a specimen on annealing. Thus Fig. 19 is a photograph of the surface of an aluminum crystal which was stretched with the generation of deformation bands, repolished, and then annealed. The anneal brought about the change of structure also shown in Figs. 17 and 18, but here this change revealed itself by a marked rumpling on the previously smooth surface. (Figs. 17 and 18 are sections almost parallel to the slip direction, Fig. 19 a section inclined to this direction.) This rumpling distinguishes the process in question from grain boundary migration, which generally does not affect the specimen surface, except for minor effects attributed to thermal etching.

This suggests that dislocation models of grain

Fig. 17 (left)—Deformation or kink band in an aluminum crystal stretched 24 pct. X250.

Fig. 18 (right)—Aluminum crystal stretched 31 pct, annealed 1 hr at 450°C, repolished and slightly stretched. X260.

Areas reduced approximately 66 pct for reproduction.

boundaries should be re-examined, since on the basis of such a model boundary migration in a specimen should affect its shape, just as polygonization of a deformation band does. The motion of a plane array of dislocations normal to itself is in fact equivalent to a shear. Fig. 20 shows this in an exaggerated fashion, and also shows how such a shear would be expected to occur under the action of an applied shear stress. Experimental data on this point might be rather informative. Indirect evidence that applied stress accelerates the motion of dislocation arrays can be found in recent experiments on creep.<sup>69, 70</sup> It was found that during the creep of aluminum, the lattice became segmented into mutually inclined "cells." This process also occurs, in the way described above, if a specimen is stretched rapidly and then annealed without applied stress, but in the latter case the segmented structure develops more slowly.

The marked effect of applied stress on polygonization is brought out clearly by the following experiment. Two specimens were cut from adjacent portions of a large crystal of aluminum which had been stretched by 20 pct, and all surfaces on both specimens were prepared metallographically. The two specimens then were placed side by side for 1 hr in a furnace at 445°C, one being subjected to a small tensile stress of 100 g per sq mm, and the other not stressed. The stressed specimen exhibited very strong surface rumplings as in Fig. 19, while the markings on the unstressed specimen were so feeble as to be scarcely visible; and this difference existed though the stress was too low to cause any trace of slip.

It is evident enough that slip is associated almost universally with the bend planes to which Dr. Jillson has redirected attention. This makes it interesting to speculate why they do not occur in certain specific cases, such as the extension of single crystals of zinc or cadmium, or of aluminum crystals of certain orientations.<sup>68</sup> I should be most interested to know Dr. Jillson's views on this problem.

Perhaps the cases just mentioned, and the instances of strongly developed deformation bands, are simply opposite extremes of a general process on the lines proposed by Dr. Jillson, i.e., in some cases deformation bands form cumulatively, in others they begin to form all the time but are constantly straightened out again. This view is strengthened by the observations that in an aluminum crystal stretched by, say, 30 pct, the strongly marked deformation bands are accompanied by numerous incipient bands which are too weak to be visible on the surface of the stretched crystals, but are rendered visible on the repolished surface by annealing.

Dr. Jillson's observations on twinning are also most elegant and striking. The thickness vs. time curves determined for the growth of deformation twins in zinc prompt several questions. Dr. Jillson accounts for the form of these curves in terms of an energy hump required to nucleate the twin which will grow catastrophically once it is nucleated because of the reduced

Fig. 20—Initial (a) and final (b) position of a bend plane subjected to a shear stress, schematic.

resistance to growth. The gradual slowing down of the growth in thickness is held to be due to the progressive relief of the stress which brought the twin into existence. But this view implies the use of a stiff spring to apply the force (a vice is effectively equivalent to this), the force in which is reduced as the specimen gives way. On the picture as stated, a twin should grow continuously to an unlimited extent under conditions of dead loading, for then no amount of twinning can relieve the stress, and a particular twin might be expected to continue growing more readily than another would be nucleated. At any rate, it would be expected that the thickness vs. time curve would have a different form in this case. It is an observed fact, however, that twins do not usually exceed a limiting thickness which varies with the particular metal. If this is followed up, it becomes apparent that there is a rough correlation between the characteristic widths of deformation twins in various metals and the shears associated with them. Thus in bismuth and tin in which the twins undergo a very small shear ( $s = 0.118$  and  $0.120$ , respectively), very coarse twins, a large fraction of a millimeter across, can be produced; while in  $\alpha$  iron, the twins, for which  $s = 0.707$ , never exceed a few microns in width, and in the face-centered cubic metals, for which the shear would be the same, deformation twins are chimeras, heard of but not seen. Now the higher the amount of shear, the more closely the atoms are forced together during the shearing process itself, and the higher the energy barrier to be overcome. It may well be that in the catastrophic first stage of the growth of a twin, cumulative strains are generated in the parent crystal adjacent to the growing twin and in the twin itself, and it may well be those stresses which set a limit to the growth of the twin. Other factors also will contribute to determining this limiting width (e.g., the closeness to which the twinning process approximates to a pure shear, which in turn depends on the crystal structure) and the correlation between this width and the shear is not perfect. Thus neither of the types of deformation twins in uranium (with shears of  $0.299$  and  $0.213$ ) ever exceed a few microns in width, though the shear is considerably less than for iron.

Another question which occurred to me is whether, when a twin is formed and destroyed repeatedly by reversing the stress, the twin always appeared in exactly the same plane and grew to the same thickness for a particular stress. If this was so, it would imply either that not all vestiges of the twin disappeared during the reverse cycle (i.e., that the twin nucleus is as difficult to erase as it is to create), or else that the twin forms at a place where the lattice is disturbed prior to the application of the stress. Furthermore, the occurrence of bend planes at the tip of a lenticular twin, as sketched in Fig. 12, should lead to a building up of permanent strain in the crystal on reverse cycling (unless indeed the formation of such bands is perfectly reversible), and this might be expected to affect the appearance of the twin as the number of cycles increased.

Finally I should like to ask Dr. Jillson how he was able to detect the very interesting instances of bend

Fig. 19—Aluminum crystal stretched 35 pct, repolished and annealed 16 hr at 435°C (under a stress of 35 g per sq mm). X30.

Area reduced approximately 66 pct for reproduction.

Fig. 21 (left)—Deformation twins in uranium section. Polarized light. X1500.

Fig. 23 (right)—Deformation twins in uranium section. Polarized light. X1200.

planes being associated with twin tips and intersections, Fig. 12. These observations go some way towards explaining something which has puzzled me for a long time, namely, how a lenticular twin can be formed at all. However, the bands must surely be extremely faint—I have certainly never been able to detect any at the extremities of twins in deformed uranium, though I am very ready to believe that they are there. It may incidentally be of interest to record here that places where twins intersect or abut on each other are not necessarily places of high strain. Figs. 21 and 22 show two fields in compressed grains of uranium, in which two families of twins cross each other with a fine disregard for each other's presence; this may be compared with Fig. 23, showing a different pair of twin families again, in which most of the twins stop short of each other in the way familiar in, say, bismuth. In the case of the smooth intersections, twins A and C intersect along a line lying in the plane of twin B, and moreover the direction and amount of shear is the same in both A and C. In the case of Fig. 21, this direction coincides with the intersection of A and C, and we have a phenomenon directly analogous to cross-slip, i.e., cross-twinning. Here twin B is formed by a shear of the first type.<sup>61</sup> In the other case, twin B is formed by a shear of the second type.<sup>61</sup> When the conditions mentioned above did not apply, the characteristic appearance of Fig. 23 was encountered.

I trust Dr. Jillson will forgive the somewhat disjointed nature of these remarks, which are put forward in the hope that they may return a tiny fraction of the stimulation which I have found in his own paper.

**D. C. Jillson**—The questions raised in your second and fifth paragraphs are answered, of course, in your sixth paragraph. I see no inconsistency between the formation and removal or flow of very slight, highly submicroscopic bends under stress and the piling up of such minute bends at a barrier of one kind or another to form a detectable bend. They might also pile up if conditions were such that the rate of formation exceeded the rate of flow. After the pile-up reaches a certain size, it might itself, as you suggest, present a barrier. I expect that in cases where deformation does not seem to result in bend planes we can assume that coalescence or piling up has not progressed to a point where the bends can be detected. If we were to deform a sufficiently perfect specimen under suitable conditions, piling up or large bends might be avoided, and bend planes might never be detected. Bend planes most certainly have been observed in single crystals of zinc extended under other conditions.

The problem is the same if you are thinking in terms of dislocations. To supply the number of dislocations required to account for plastic flow, assumptions of generation at the surface, or of reflection, or of multiplication have been made. I suggest that rumpling may afford a mechanism for the generation of dislocations within a crystal and that there seem to be reasons for giving serious attention to this possibility:

In regard to the thickness of mechanical twins, I expect that in the unattainable case of a perfect crystal

in a perfect setup, such that a single twin might form and grow without restraint and without the introduction of any other deformation, dead loading would cause unlimited growth without the nucleation of another twin. The rough correlation between widths of twins and the shears associated with twinning is probably a result of constraints, and I would expect the width of twin for a given metal to vary with the conditions determining the degree of constraint.

The question of whether a twin recurs on exactly the same plane upon repeated twinning and detwinning could not be answered experimentally because other deformations were always introduced. Had the specimen been perfect and had no other deformation been introduced, the shearing should have started between the planes where the stress was the highest, and if the experiment could have been carried out perfectly, this should have been the same place every time.

The specimen represented in the bottom sketch in Fig. 12 was obtained by compressing a smooth cylindrical specimen in which the basal plane was perpendicular to the specimen axis. The resultant markings were quite clear on the cylindrical surface. The markings of the middle sketch, too, were clear enough on the smooth surfaces of a deformed specimen of square section. The nature of the markings shown in the top sketch was deduced from observations of the markings on basal faces cleaved before the specimen was twinned. It was noted that if the twin went all the way through the specimen, there was no adjacent bend, but that if the twin did not, being then of a presumably lenticular shape, there was an adjacent bend in the surface. The sketch represents what we believe to be a logical rationalization. We did not observe this on a polished section such as shown in the sketch because the actual bend was very slight. The difference in the reflection of light from the basal surface, however, was quite definite.

# A Study of the Plastic Behavior of High-Purity Aluminum Single Crystals at Various Temperatures

by F. D. Rosi and C. H. Mathewson

DISCUSSION, B. Averbach presiding

**P. A. Jacquet** (Paris, France)—The authors state on p. 1163: "It is known that the oxide film which forms very rapidly on electrolytically polished aluminum in contact with air has a disturbing effect on the appearance of slip bands, making them wavy rather than straight."

Actually the oxide layer which builds itself in the air on an aluminum surface electropolished in the proper way is extremely thin—it is not visible by electron diffraction as observed by H. Raether<sup>28</sup>—and cannot have any effect on the slip bands.

On the other hand it is well known that some polishing baths which contain fluoboric acid, phosphoric acid, nitric acid, etc., lead to the building up of a thick oxide layer during the polishing. Thus with such an electrolyte aluminum comes out of the bath already oxidized, whereas with a  $\text{ClO}_4\text{H}$ -acetic anhydride bath the metal is practically un-oxidized when taken out and then is covered rapidly with a 20A thick layer which subsequently grows very slowly.

G. R. Wilms has shown that the thick alumina layers built up during polishing in the above-mentioned electrolytes hinder the observation of aluminum surface deformation. He determined also that the same cause of error does not exist with a metal polish in perchloric acid-acetic anhydride bath.

**F. D. Rosi** (authors' reply)—Dr. Jacquet is quite right in pointing out that the difficulty encountered in observing deformation markings is a direct result of the oxide layer developed during the electrolytic polishing. It was not intended to attribute the degree of thickness of the oxide layer entirely to specimen contact with the atmosphere. In fact, it was mentioned in the paper that "the nature of the oxide film depends to a great extent upon the electrolytic polish used, and perhaps unintentional variations in the technique of polishing." From the observed results, we strongly believe that the oxide film resulting from polishing in a methyl alcohol-nitric acid bath is not deleterious to the observation of slip markings in high-purity aluminum. Like Dr. Jacquet, we, also, have found that polishing in a fluoboric acid bath makes the examination of surface markings difficult.

**N. K. Chen and R. Maddin** (Johns Hopkins University, Baltimore)—The results recorded in this paper are very interesting; in particular, we would like to refer to the authors' Fig. 10, in which is shown the effect of increasing strain on the density of slip bands in the early stages of plastic flow. Although it is apparent from the curves that the orientation of the crystals has a marked effect on the density of slip bands for a given amount of strain, no particular orientational relationship seems to have been established.

One of the discussers (N. K. Chen) has made a structural study of aluminum single crystals of many orientations after plastic extension. Most aluminum single crystals exhibit slip lines with a reasonable regularity of spacing, together with deformation bands. However, there is an area of orientation, spreading out from the  $\langle 111 \rangle$  pole of the Taylor and Elam triangle, in which flexural gliding seems not to occur and slip lines are spaced much more irregularly, assuming a strongly clustered appearance,<sup>29</sup> Fig. 23. By simple comparison it is apparent that crystals with clustered slip lines will give a smaller density of slip markings upon measurement.

Thus it is noticed that in the authors' Fig. 10 crystals G and E, which exhibit a much smaller number of slip bands per mm than the crystals T and H at the same amount of strain, are both oriented with their stress axes near  $\langle 111 \rangle$ , the particular area discussed above. Since strain hardening did not appear to vary with the

Fig. 23—Effect of orientation on distribution of slip bands on extended tapered aluminum single crystals. X1.

orientation of the crystal, and thus could not be used as a clue in this case to explain such fundamental difference of the appearance of slip bands, the nature of lattice rotations, such as the generation of deformation bands, and operations of conjugate and cross-slip systems, may be considered as one probable cause.

For example, it has been shown by Heidenreich<sup>30</sup> that in aluminum the glide lamellae are about 200A thick and have been displaced about 2000A. For equal amounts of strain it would appear that the displacement of lamellae must vary if the density of the slip bands is to change with the orientation.

If crystals such as the authors' G and I, extended the same amount, are to have a vastly different density of slip bands, then either the displacement of the bands in the different crystals in question must vary or other factors such as the action of collateral slip systems and the formation of deformation bands retard the classical lattice rotation of one of these crystals (the one having the greater number of slip bands), so that both result in the same amount of strain.

**F. D. Rosi**—The observations of Drs. Chen and Maddin on the change in the character of slip markings for a specific orientation might account, in part, for the differences found in the density of slip bands for crystals of different orientation. It would be interesting to know more details regarding the nature of the clustering; for example, if it is similar to that observed in  $\alpha$  brass crystals. On their basis, however, it is difficult to explain the similarity in density of slip bands (particularly for small strains) between crystals E and H, which have markedly different orientations. The character of the slip bands in these two crystals (as well as in crystal A) were quite similar; and, in contrast to crystal T, they appeared thicker and did display a minor tendency for dense clustering in some regions. Furthermore, in crystal T there was a greater evidence of the segmented type slip, reported and described in the paper as characteristic of deformation at lower temperatures. In view of the recent electron microscope studies of slip bands by Heidenreich and Shockley,<sup>31</sup> these observations do suggest that the amount of shear per slip band in crystals E, H, and G is greater than in T for a given amount of extension.

Recent experiments on single crystals of different metals at Sylvania Laboratories suggest a correlation between the nature of slip markings and changes observed in the shear hardening curve in regions of small plastic strain. These results also have emphasized a

definite need for more systematic and detailed studies of the nature of slip markings in single crystals possessing critical orientations.

**C. Crussard** (*Ecole des Mines, Paris, France*)—It is a very interesting fact that the aluminum crystals prepared by the authors by solidification display the same properties as the one I have made by recrystallization, regarding the discontinuous or steplike formation of slip bands.

The shape of the stress-strain curves observed by the authors on their crystals is also very similar to that of our recrystallized single crystals,<sup>32</sup> when only one glide system is active at the beginning. After 1 pct elongation, the new rise in our curves has been related by us to a strong increase in asterism and to the formation of deformation bands. It would be interesting to know if the same rise in the curve exists for the authors' crystals. In the case where two glide systems are active right from the beginning, we have observed a different shape of the stress-strain curve: It is parabolic from the beginning as has been postulated by G. I. Taylor; the asterism is stronger at the beginning than in the general case, but weaker at about 10 to 20 pct elongation, because no deformation bands are formed.

It is interesting to point out that the shape of stress-strain curves obtained by the authors on fused crystals seems in contradiction with the well-known experiments of Dehlinger and Gisen. The latter seems also in contradiction with some newer observations regarding the state of perfection of the crystals as shown by A. Guinier and myself.<sup>33</sup> Thus, it would be extremely interesting to have some X-ray information on the crystals used here by the authors, regarding the state of perfection of each of the subgrains of the lineage structure, for orientation (e.g. by Guinier's method) and intensity of reflection.

**F. D. Rosi**—Dr. Crussard's comments are both interesting and gratifying. It is significant to find that aluminum single crystals of similar purity produced by critical recrystallization show properties similar to those prepared by solidification from the melt. If structural irregularities are at the bottom of most plastic phenomena observed in real metals, then there can be no serious difference in the imperfections resulting from these two modes of single-crystal production of high purity metals.

With regard to a change in the shear hardening of these stress-strain diagrams, we also have observed a gradual rise in the curves at room temperature after an extension of about 0.4 pct. However, this value of extension appeared to vary with orientation, being somewhat less for those orientations nearer the [100] and [111] poles. At the temperature of liquid nitrogen this change of slope was not observed. Recent experiments on the extension of high purity silver single crystals (to be published) show a similar, but more marked inflection in the shear hardening curve after small amounts of extension (approximately 0.7 pct). Furthermore, a temperature dependence of this unique behavior has been fairly well established.

The extent of the X-ray studies was confined to ordinary back-reflection photograms, which were taken at various points along the circumference of the specimen. In general no asterism was observed up to extensions of approximately 1.5 pct for the room temperature tests. In view of the X-ray techniques used, no detailed study of structural imperfections in these crystals was possible. The only evidence of structural irregularities was the occasional presence of double diffraction spots indicative of the lineage imperfections. As mentioned in the paper, the angular spread

of these spots was never observed to exceed 2°.

It appears that the essential difference in the stress-strain diagrams reported by Dehlinger and Gisen on aluminum crystals prepared by solidification and those of the present investigation is in the sharpness of the yield point. In the case of the former, the yield point was ill-defined, which might very well be attributed to the lower purity of the metal, for, perhaps, the same reason that the yield point becomes less accentuated with decreasing temperature. Furthermore, it is quite possible that this same effect of increasing purity may be responsible for the rise in the stress-strain diagram after small extensions reported in the present investigation, but not observed by Dehlinger and Gisen in the less pure material.

**W. C. Ellis** (*Bell Telephone Laboratories, New York*)—Important new information for plastic behavior at several temperatures was reported in this paper for tests carried out with a nearly constant rate of stressing. Similar work has been done by other investigators using a constant strain rate. When a constant stress rate is used the strain rate is not necessarily constant over the range of a single test and usually is not. However, as shown in Fig. 5 of the paper, the strain rate is essentially constant in the plastic range for the individual tests. For tests at different temperatures, however, the strain rates are appreciably different, being substantially higher for the tests at 353°K. The importance of strain rate would seem to be that the recovery processes, being time dependent, are linked to the rate of straining—a faster rate permitting less recovery. Recovery in these tests would have been influenced not only by the different temperatures used, but also by the different strain rates. The latter may have been only minor although we do know that recovery proceeds (at least to some degree) in high purity aluminum at quite low temperatures. I should like to ask the authors to what extent they believe a varying strain rate may have affected the results and what the strain rates were in the tests?

**F. D. Rosi**—Dr. Ellis' question as to the effect of different strain rates at the different temperatures of testing on the results reported in this paper is indeed one worthy of consideration. It has been fairly well established that the speed of stressing has an insignificant effect at low temperatures and near the melting point, but a rather marked influence in an intermediate range of temperature. As Dr. Ellis points out, for aluminum of such high purity, this temperature range, where time effects are important, might very well be from room temperature to 200°C. Nevertheless, in view of previous investigations on the effect of strain rates on such fundamental properties as the critical shear stress and the coefficient of shear hardening, it appears very unlikely that this factor would affect these properties to an appreciable extent under the conditions of the present investigation, where the strain rate only varied by a factor of 5 over the temperature range of testing, see Table V. For example, in tests on aluminum at room temperature Weerts<sup>34</sup> found that on varying the speed of testing from 1:23,000 (450 pct elongation per sec) glide began at approximately the same stress, and the shear hardening increased by only 16 pct. In fact, even for hexagonal metals where this effect of varying strain rates appears to be more significant, a hundred-fold increase in the speed of testing is necessary to produce an increase in the critical shear stress of 20 to 30 pct. As corollary evidence, very recent experiments with high purity (99.99 pct) silver single crystals showed that a two-fold increase in the speed of stressing (for rates comparable to the experiments with aluminum) showed no change in the values for critical shear stress or coefficient of shear hardening.

## A Study of the Strain Markings in Aluminum

by Bani R. Banerjee

DISCUSSION, B. Averbach presiding

**R. G. Treuting** (Bell Telephone Laboratories, New York)—The author is first to be congratulated on a careful technique that has demonstrated the occurrence in aluminum at low temperatures of the strain markings observed in other face-centered cubic metals at normal temperatures, and the thermal instability of these markings.

In view of his findings, the author's hypothesis that either a stacking fault or an extended dislocation introduced by low temperature deformation has an associated energy higher than in other face-centered cubic metals is, as he says, logical, and worthy of some further comment:

1—The ratio of twin interface tension to grain boundary tension in aluminum has been found to be significantly higher than in copper.<sup>11</sup> To the extent that the respective grain boundary tensions are comparable, the twin interface tensions differ correspondingly. This would presumably apply in similar degree to twin faulting. Barrett<sup>12</sup> has also concluded from X-ray line width data that the faulting energy of aluminum is large.

2—R. D. Heidenreich<sup>13</sup> has found by electron microscopy that polygonization<sup>14</sup> of deformed aluminum occurs at the temperature of liquid nitrogen,  $-196^{\circ}\text{C}$ . Hence the recovery process proceeds at the temperature of the present experiments,  $-72^{\circ}\text{C}$ , probably at a significant rate.

3—There is evidence, e.g., Maddin, Mathewson, and Hibbard<sup>7</sup> that recrystallization twin bands are aligned with previous slip lines. This has been interpreted as indicating that slip generates twin faults in accordance with Mathewson's hypothesis. However, recent work by Burke<sup>15</sup> suggests strongly that twin faulting from slip cannot be the only source of twin bands observed in substantially recrystallized metals. The absence of twin bands in recrystallized aluminum may require further explanation than the thermal relief of twin faulting.

It would seem that a critical experiment is still needed to determine whether twin faulting is produced by slip. The method employed by Barrett<sup>16</sup> to establish stacking disorders in the Cu-Si system may profitably be applied to deformed metals, if a sufficient proportion of presumptively faulted planes can be generated without introducing so much lattice distortion as to obscure the X-ray data. This might be accomplished by a deformation mechanism permitting continuous or periodic shifting of the applied stress axis to maintain the pole of the latter within a single stereographic triangle of the single-crystal specimen projection.

The writer is indebted to his associates W. T. Read and R. D. Heidenreich for helpful discussions with respect to these comments.

**P. A. Jacquet** (Paris, France)—For the first time we succeeded in detecting "strain markings" far below the surface of a copper specimen which had been deformed by as small an amount as 1 pct in extension.<sup>17</sup> The observations of these markings is solely due to the sensitivity of the etchant. Thus with brass and other copper alloys a sodium hyposulphite electrolytic etch is far more sensitive than any other etch by known standard reagents.<sup>18</sup> With copper the most sensitive method is a short-cut etch into the electropolishing bath (phosphoric acid).

With aluminum bronze, some strain markings seem to correspond to microtwins, Fig. 6. With brass, the etch (Fig. 7) probably shows the regions where there are numerous whole sets of gliding lamellae which

Fig. 6—Aluminum bronze annealed plate. X1600.

Surface abraded with emery paper No. 1. Electrolytic polishing to dissolve 15 micron thickness. Anodic etching in sodium hyposulphite at 0.4 pct. Strain markings show up as parallel striation systems oriented at  $60^{\circ}$ , on which a little element—which seems to be microtwins—can be seen.

form each slip line visible on the polished surface before etching.

The author stresses the importance of avoiding any heating for strain-marking observations, for instance mechanical polishing is performed by frequent coolings of the specimen down to  $-72^{\circ}\text{C}$ . But it is certain that during electropolishing a substantial superficial heating takes place, especially in the process described with No. 1 electrolyte where the current density is of the order 100A per sq decimeter.

Even with electrolyte No. 2 (described as  $\text{HClO}_4$ -acetic acid in the footnote, p. 1126, and  $\text{HClO}_4$ -acetic anhydride in Table I) an increase of the temperature exists. How does the author reconcile these two contradictory features?

**B. R. Banerjee** (author's reply)—The author is indebted to Dr. Treuting for his interesting comments, particularly for pointing out some recent experimental results tending to substantiate the author's hypothesis.

The author would also like to thank Dr. Jacquet for

Fig. 7—Annealed  $\alpha$  brass. X1600.

Surface abraded with emery paper No. 2, then electropolished (dissolution 0.24 mm), final anodic etching in 0.1 pct sodium hyposulphite solution. The lower distinct diagonal line is a twin boundary.

his remarks. Although a small local heating undoubtedly does occur during electrolytic polishing, the constant contact with the cool electrolyte, and the short duration of polishing time, presumably help to keep the temperatures sufficiently low to prevent excessive recovery.

The author would like to correct the discrepancy pointed out by Dr. Jacquet. The electrolyte No. 2 was perchloric acid and glacial acetic acid.

## Activation Energy for Recrystallization in Rolled Copper

by B. F. Decker and D. Harker

DISCUSSION, R. Maddin presiding

**F. H. Wilson** (*American Brass Co., Waterbury, Conn.*)

—The authors are to be congratulated for employing a simple and direct technique for measuring the extent of recrystallization. By this method they are sure that they are determining the activation energy for recrystallization alone, uncomplicated by strain relief or other effects associated with recovery which hamper interpretations when the changes in other quantities during annealing are measured.

They tacitly assume that only the orientations which constitute the deformation texture and the "cubic" recrystallization texture are involved, and this assumption is related directly to the question of the origin of recrystallization textures concerning which opinions are still in conflict. It would be expected that their specimens showing maximum intensity from (200) planes reflections, having been rolled 98 pct, would have microstructures which show them to be 100 pct in the cubic orientation. Did they confirm this? Assuming this to be true, it would appear to be possible to employ the authors' data to determine whether the recrystallization texture resulted from "oriented nucleation" or from "oriented growth."

The value for the percentage of material transformed as derived from measurements of loss in intensity of (111) reflections would be independent of the orientations of the transformed material (except for the remote possibility that an appreciable number of the new nuclei would have [111] poles oriented the same as the deformation texture). However, the value as derived from measurements of gain in intensity of (200) reflections would depend upon whether the nuclei were all in the "cubic" orientation or whether other orientations formed. The values as derived from both sets of measurements would be equivalent throughout only if the nuclei formed in the "cubic" orientation. If values derived from (200) reflections are consistently lower at the start of recrystallization than those derived from (111) reflections, there would be some support for the theory of "oriented growth."

It would be of considerable value in contributing to our understanding of the mechanism of recrystallization if the authors could submit data to show the extent of agreement between the two sets of intensity measurements.

**M. Balicki** (*Polytechnic Institute of Brooklyn, Brooklyn, N. Y.*)—In 1937, A. Krupkowski and M. Balicki determined the activation energy for recrystallization of cold deformed copper<sup>5</sup> from both isothermal and isochronal experiments on cold-drawn commercial copper, using the change in mechanical properties as an index of structural changes. The values then obtained (32 and 31.5 kcal per mol) within the limit of accuracy, are identical with the figures obtained by the authors for OFHC copper (29.9 kcal per mol). M. Cook and T. L. Richards<sup>6</sup> in 1946 obtained values for the activation energy for copper of the order of 43 to 48 kcal per mol that are different from the values

found by the authors and in ref. 5 because of the employment of a different formula. It has been shown, however, that the isochronal annealing experiments performed by Cook and Richards yield values between 30.4 and 32.4 kcal per mol,<sup>7</sup> if treated by the method of Krupkowski and Balicki.<sup>8</sup> These figures compare well with the ones reported in the present paper for OFHC copper.

L. R. Jackson, A. M. Hall, and A. D. Schwoppe<sup>9</sup> used a value of 30 kcal per mol for the activation energy for the recrystallization of copper and the treatment of Krupkowski and Balicki to predict successfully the prolonged isothermal annealing behavior of various commercial grades of copper from the experimental data of short duration isochronal annealing.

The method adopted by the authors for heat treating isothermally is limited to relatively short times performed at relatively high temperatures, since changes in barometric pressure during prolonged treatments will affect the boiling points of the liquids used as an annealing medium and cause a fluctuation in the temperature. Did the authors perform their anneals at times when the barometric pressure was the same and did they note any deviations from the nominal annealing temperature by direct measurements? The quite feasible slight deviation from the nominal annealing temperatures would materially affect the location of the experimental points in Figs. 1, 2, and 4, so that the curves (with the exception of the last one in Fig. 4) might not give a true picture of the progress of re-annealing, and the two middle curves in Fig. 4 might be curved due to this cause.

Finally, the method is based on the assumption that during the recrystallization there is a change in orientation. As far as I know there is no proof that recrystallization will always bring about a different orientation from that of the cold deformed matrix. The accuracy of the method, therefore, will depend upon many factors which influence texture formation and will vary from case to case, such as: 1—Degree and character of impurity atoms present, 2—amount and character of alloy elements present, 3—the degree of cold work, 4—the mode of plastic deformation, 5—grain size and randomness produced by penultimate anneal, and 6—susceptibility to self-annealing during cold deformation and subsequent storage. Thus, a question arises about the accuracy of this new method and whether or not the degree of accuracy is the same for both types of copper tested. As a consequence, one is left wondering whether the differences in activation energy of 29.9 and 22.4 kcal per mol found by the authors are real or due to the systematic error of the method.

**B. F. Decker** (authors' reply)—Dr. Wilson's suggestion that knowledge of the agreement between measurements of the appearance of recrystallized material and the disappearance of cold-worked material would contribute to an understanding of the mechanism of recrystallization is well taken. The authors have not correlated data of this type for copper. However, Seymour and Harker<sup>6</sup> in their studies of 50 Fe 50 Ni alloy did

obtain both kinds of data. Their results are shown in Figs. 1 and 2 of their paper. For a given time and temperature there is good agreement between values obtained by the two methods for amount of material recrystallized. This would rule out the possibility that the texture sharpened by ordinary grain growth after recrystallization.

No microstructural investigation was made of the copper samples studied.

The authors thank Dr. Balicki for his interest in and comments on this paper, but they believe that his criticism of the accuracy of the method is not justified. All heat treatments in the boiling organic liquid at any one temperature were made on the same day, and temperature checks were made frequently with a calibrated thermometer. A temperature shift greater than  $0.5^\circ$  was never found and shifts of  $0.5^\circ$  only rarely. Consequently, the accuracy of the experimental points in Figs. 1, 2, and 4 is not affected materially by the method of annealing, and the shapes of the curves in Figs. 4 and 5 are real.

The authors admit that this method is not applicable to cases of recrystallization without change in orientation. However, primary recrystallization in copper is not such a case.

In reply to Dr. Balicki's suggestion that the difference in activation energy of 29.9 and 22.4 kcal per mol is due to error in the method, analysis of the data

shows that the maximum deviation of  $Q$  for the pure copper is 1.1 kcal per mol and for the OFHC copper 1.7 kcal per mol. Therefore, the maximum experimental uncertainty (2.8 kcal per mol) in the difference in activation energy for the two kinds of copper is very much less than the measured difference of 7.5 kcal per mol.

## Recrystallization Reaction Kinetics and Texture Studies of a 50 Iron 50 Nickel Alloy

by William E. Seymour and David Harker

DISCUSSION, R. Maddin presiding

**A. A. Burr** (*Rensselaer Polytechnic Institute, Troy, N. Y.*)—I would like to say a few words about this interesting method of applying the X-ray spectrometer to measuring structural changes in metals. As the authors of both papers just presented\* have pointed out, the success of the method depends on the fact that: 1—The spectrometer when set up as described, measures diffracted energy only from planes parallel to the face of the specimen. 2—A high degree of preferred orientation exists in the specimen initially and a change in grain orientation occurs as the process under study proceeds.

I would like to point out another metallurgical problem where the same principles have been utilized. In some work done in 1943 at the Pennsylvania State Col-

lege<sup>9</sup> involving the interdiffusion of thin films of copper and zinc, an analogous setup was used to follow the diffusion process and to verify the Widmanstätten relationships between the phases in this system. In this case the zinc film exhibited a high degree of preferred orientation with the basal planes parallel to the glass substrate. As the structure changed with diffusion at relatively low temperatures the breakdown of the zinc structure and the growth of that of  $\beta$  brass could be followed. From the preferred orientation of the resultant brass the Widmanstätten orientation relationships could be determined.

**W. E. Seymour and D. Harker** (authors' reply)—We are very grateful to have been reminded by Professor Burr of the work done by him and others at Pennsylvania State College, using X-ray diffraction methods similar to ours; our failure to give reference to this work was due entirely to oversight.

\* This refers to paper by B. F. Decker and D. Harker, the discussion of which is on p. 548, this volume, and this paper.

## The Textures of Cold-Rolled and Annealed Titanium

by Howard T. Clark, Jr.

DISCUSSION, R. Maddin presiding

**M. K. Yen and J. P. Nielsen** (*New York University, New York*)—We wish to compliment Dr. Clark on his excellent work and interesting results. The double texture reported in this paper was found to be in good agreement with our results on iodide titanium after 97.75 pct reduction by cold rolling.<sup>8</sup> The rolling texture was characterized by a clustering of the (0001) poles around two axes lying in the transverse plane and inclined at  $30^\circ$  to the rolling plane. The average grain orientation for the specimen could be shown schematically as in Fig. 4. Moreover, this double texture also was found in iodide titanium deformed by compression. The usual [0001] compression texture occurring in h.c.p. metals was observed for reductions up to about 85 pct. However, a pronounced double texture comparable to that shown in Fig. 1c of Dr. Clark's paper was obtained

when a specimen was subjected to compression rolling totaling about 94.5 pct. The difference in preferredness between the center and the surface material in compression rolled specimens also was studied. The results

Fig. 4—Schematic diagram of average grain orientations of  $\alpha$  titanium after a reduction of 97.75 pct by cold rolling.

Table II. Types of Pole Figures for Various Rolled Close Packed Hexagonal Metals

| Metals | C:A Ratio | Type of Scattering                                           | Reference                                                    |
|--------|-----------|--------------------------------------------------------------|--------------------------------------------------------------|
| Zn     | 1.856     | 20°-25° toward rolling direction                             | Caglioti and Sachs <sup>9</sup>                              |
| Cd     | 1.885     |                                                              | Valouch <sup>10</sup>                                        |
| Mg     | 1.624     | i. Equal scattering<br>ii. Slightly toward rolling direction | Schmid and Wassermann <sup>11</sup><br>Bakarian <sup>2</sup> |
| Zr     | 1.590     | Scattering toward transverse direction                       | Burgers and Jacobs <sup>1</sup>                              |
| Ti     | 1.587     |                                                              | Clark, <sup>12</sup> Yen <sup>8</sup>                        |
| Be     | 1.568     |                                                              | Smigelskas and Barrett <sup>3</sup>                          |

obtained were similar to those of Dr. Clark on straight rolling, i.e., the center material had a more pronounced double texture than did the surface material.

In the case of wires by rolling for 85 pct reduction in area, the following planes were found to lie perpendicular to the wire axis, in the order of prevalence: (1010), (1011), and (0001). A relatively sharp [1010] texture was observed in a wire specimen reduced 92 pct in area.

If we make a correlation of the type of distribution of the basal planes in the pole figure with *c:a* ratio, as in Table II, we find that the first group, Zn and Cd (*c:a* > 1.633), has a scattering toward rolling direction and that the third group, Zr, Ti, and Be (*c:a* < 1.633) has a scattering toward transverse direction. In the case of Mg, the *c:a* ratio is quite close to 1.633, and it exhibits both directions of scattering although a scattering tendency has been reported similar to that of

the Zn and Cd group. The variations in the reported Mg results may be accounted for by slight changes of *c:a* ratio around the ideal 1.633 value due to the presence of impurities.

The scattering in the rolling textures of the metals listed in Table II may be related to twinning as well as to the *c:a* ratio. For Zn and Cd, twinning results in elongation along the twinning direction and for Zr, Ti and Be, twinning produces a shortening in the twinning direction. For the first group the flow of metal would be assisted by twinning along the rolling direction and thus twinning might be related to the scattering toward the rolling direction. Dr. Clark has pointed out that twinning on the (1102) planes of Ti would yield a thickening of the metal. However, since twinning in Zr, Ti, and Be produces a shortening which is inconsistent with the flow of the metal, its relative occurrence would be greater in the transverse direction than in the rolling direction. This type of twinning then would be related to the observed scattering toward the transverse direction.

It is also interesting to note that at certain orientation at which the twinning plane in h.c.p. metals is parallel to the rolling plane, e.g., the basal plane of Ti makes an angle of 42°30' with the rolling plane, twinning may occur with no change in thickness of the metal.

## Production and Examination of Zinc Single Crystals

by D. C. Jillson

DISCUSSION, R. Maddin presiding

**A. J. Goss and S. Weintraub** (*University College, Southampton, England*)—We have read Dr. Jillson's paper with considerable interest, particularly as we consider any detailed information with regard to the growth of metal crystals of extreme importance. Recently we have carried out a similar comprehensive investigation of the influence of temperature gradient and rate of growth on the successful production of single crystals of tin. A brief report of the results obtained will appear shortly in *Nature*. Andrade and Roscoe's method<sup>12</sup> with a horizontal traveling furnace was used, and the crystals were grown from the melt, in vacuo, in pyrex glass tubes. More recently we have turned our attention to zinc, and the results of our preliminary experiments on 99.95 pct purity Zn may be of interest. Each specimen of zinc before crystallization was in the form of a cast rod 25 cm long and 5 mm diam and was contained within an open pyrex glass tube of approximately 7 mm internal bore. The specimen and its surrounding glass tube was placed inside the furnace tube where a vacuum of the order of 10<sup>-2</sup> mm Hg was maintained, during the process of crystallization. Various speeds of growth and temperature gradients were tried. The yield of good single crystals was 13 out of 15 specimens, 3 out of 11, and 0 out of 9, for 0.5, 1.5, and 5.3 mm per min speeds of growth, respectively. In the imperfect specimens the structure usually consisted of several parallel separate crystals along the length of the rod. It should be noted that the slowest speed used, namely 0.5 mm per min is slightly greater than that corresponding to 8°C per in. and 7.4°C per hr for which Dr. Jillson obtained 100 pct yield.

It is stated by Dr. Jillson that preferred directions of crystal growth in zinc crystals may be influenced by very small amounts of impurities. For 99.99+ pct pure Zn he found a preference for the basal planes to be within 20° of the perpendicular to the specimen

axis; but for 99.999+ pct pure Zn, they were randomly orientated. We have found that for 99.95 pct Zn there is a marked preference for the angle between the *c*-axis, [001], of the successfully grown crystal and the specimen axis to be 70° to 90°. From suitable test temperature measurements that we have taken, it would appear that the direction of heat flow is along the specimen axis. It would be desirable to test further whether impurities are a controlling factor on the orientation, and we are extending our experiments to purer zinc.

The opinion has been expressed by those who have used methods for the production of metal single crystals in which the metal is held vertically, that the pressure of the superincumbent metal does not affect the crystal growth. However, we believe that this is still a matter of some doubt and would question whether, in addition to the proper direction of heat flow and impurity content, the presence of some 20 in. of superincumbent metal as in Dr. Jillson's case is not also a determining factor affecting the growth and possible orientation of the single crystal.

For the determination of the orientations of our zinc single crystals, we use the optical reflection method described by Chalmers,<sup>13</sup> and we have found that the thermal etching due to the normal vaporization of the crystal gives sharper reflection patterns than any of the chemical etchants mentioned by Dr. Jillson. We would recommend the use of the thermal etching. Nevertheless we do regard Dr. Jillson's results obtained by chemically etching the surface as of considerable interest and importance.

We would be glad to have more detailed data of the various speeds of growth and temperature gradients used by Dr. Jillson so as to check whether there is any relation between these two quantities and the yield of single crystals.

**E. S. Greiner** (*Bell Telephone Laboratories, New York*)—Crystal imperfections such as lineage result in

increasing the angular spread of back-reflection Laue spots. Since the ridges on the surface of the crystal shown in Fig. 5 of the paper may be evidence of lineage in the zinc, I wish to ask the author if he observed any significant difference in the angular spread of back-reflection spots depending on whether the X-rays were reflected from a ridged or a smooth area of the surface. Was there any change in the angular spread of corresponding Laue spots reflected from various areas of the crystal surfaces? This information would aid in evaluating the perfection of these zinc crystals.

**G. Edmunds** (*American Brake Shoe Co., Mahwah, N. J.*)—The author has observed a wide range of orientations of the single crystals produced from 99.999 + pct Zn and has suggested "a possibility that preferred directions of crystal growth in zinc crystals may be influenced by very small amounts of impurities." What seems to be a more likely explanation of the occurrence of random orientations is that the perfection of Dr. Jillson's experimental technique, together with the small content of impurities that might nucleate growth, has resulted in only one nucleus being a center of crystallization. Except insofar as nuclei might tend to be oriented preferentially, this should lead to randomness of crystal orientation. Under less perfect experimental conditions more centers of crystallization would be expected, and there would be a tendency for those crystals to survive and extend whose [210] direction (nearly<sup>14</sup> the direction of maximum growth rate) most nearly paralleled the direction of the maximum thermal gradient. Thus, it seems logical to expect more randomness of orientation in exceptionally pure metal, but not an influence on the preferred direction of crystal growth as suggested by Dr. Jillson.

**D. C. Jillson** (author's reply)—The data of Goss and Weintraub suggest better yields at lower growth rates, but do not show the separate effects of temperature

gradient and cooling rate. A high cooling rate and temperature gradient can give the same growth rate as a low rate and gradient, but might give different results. We have not run enough tests with high or low temperature gradients or at high cooling rates to draw conclusions as to relative probabilities of success. We believe that success depends largely upon control of nucleation and that purity is a very important factor. With higher purity, the range of conditions for successful growth may be wider.

The data of Goss and Weintraub on orientation preferences in specimens of lower purity seem to support our own very meager data suggesting a possible influence of impurities on preferred direction of crystal growth. The arguments of Mr. Edmunds against this are very logical, but might be qualified to read "there would be a tendency for those crystals to survive and extend which have a direction of maximum growth rate (nearly [210] in zinc of 99.99 + pct purity or less) most nearly parallel to the direction of the maximum thermal gradient." Lacking definite data on growth rates in different directions in zinc of higher purity, and considering the present data and other data more recently brought to our attention, we feel that the question might be kept open.

We are sorry that we cannot answer Dr. Greiner's question regarding the angular spread of back-reflection spots from the ridged areas, because we prepared no back-reflection patterns of these areas. They were relatively lead-rich areas and we attributed the ridges to lead segregation.

## The Structure of Intermediate Phases in Alloys of Titanium with Iron, Cobalt, And Nickel

by P. Duwez and J. L. Taylor

DISCUSSION, B. D. Cullity presiding

**E. S. Greiner** (*Bell Telephone Laboratories, New York*)—In order to reveal the presence of ordering in alloy systems by the X-ray technique, the superlattice reflections must be of sufficient intensity for detection. If the scattering powers of the elements in the alloy are quite different, e.g., Cu-Au or Fe-Si, the reflections from the superlattice are intense and can be detected by usual X-ray procedures. If, however, the alloys are composed of elements whose atomic numbers differ by one or two, e.g., Cu-Zn, Fe-Co, or Fe-Ni, the superlattice reflections are very weak because of the small differences of scattering powers. In these cases it is necessary to select the radiation so as to obtain differences in scattering powers of the elements in the

alloy, which are sufficient for the production of superlattice reflections. The method of selection has been described in the literature.<sup>10</sup>

The present paper describes X-ray tests which did not reveal ordering in Ti-Fe, Ti-Co, and Ti-Ni alloys, the atomic numbers of whose elements differ by 4, 5, and 6, respectively. I wish to ask the authors if one must select a favorable radiation to be certain of the detection of order, if present, in alloys such as these.

**P. Duwez and J. L. Taylor** (authors' reply)—It is true that by means of a proper choice of radiation it is possible to increase the difference between the scattering factors of two atoms in a crystal. This method, however, has not been used in the present investigation. It is therefore possible that very weak reflections were not detected on the X-ray diffraction patterns and more careful measurements might reveal the existence of an ordered structure in the TiFe, TiCo, and TiNi phases.

## On the Martensitic Transformation at Temperatures Approaching Absolute Zero

by S. A. Kulin and Morris Cohen

DISCUSSION, A. R. Troiano presiding

**J. C. Fisher, J. H. Hollomon, and D. Turnbull** (*General Electric Co., Schenectady*)—The authors have done an excellent piece of work in demonstrating that martensite plates form rapidly in stainless steel at a temperature of 4°K. According to the relationship:

$$\text{Rate} = v \exp(-Q/RT) \quad [1]$$

an appreciable growth rate at 4°K corresponds to an activation energy  $Q$  of 100 cal per mol or so at the most. Using this argument, they have suggested that the atom-by-atom growth mechanism proposed for

martensite probably is incorrect, and that a growth mechanism analogous to the propagation of sound waves is more likely.

The authors' observations are not in agreement with those of Kurdjumov and Maksimova, who report an activation energy  $Q_m = 1600$  cal per mol for the growth of martensite in 0.6 pct C, 6 pct Mn steel, and near cessation of the martensite transformation below -200°C in this alloy. However, it may be possible to reconcile the two sets of observations.

The zero-point energy of a mol of crystalline solid is  $E_0 = (9/8) R\theta_D$ , according to the Debye model, where  $\theta_D$  is a constant in the neighborhood of 10°.

This energy is split up among modes of vibration having energies varying from nearly zero to about  $(3/2) R\theta_D$  cal per mol, raising a question as to the validity of eq 1 except for values of  $Q > (3/2) R\theta_D$ . For iron,  $\theta_D = 420^\circ\text{K}$ ,  $E_0 = 950$  cal per mol, and  $(3/2) R\theta_D = 1260$  cal per mol. Hence, whenever  $Q$  is in the neighborhood of 1000 cal per mol in iron, the zero-point energy may be sufficient to allow the process to continue at  $0^\circ\text{K}$  by the tunnel effect.

If the activation energy  $Q_m$  for the unit process of the martensite transformation, thought of as an atom-by-atom process, is a function of composition, it may be possible to vary  $Q_m$  from a relatively large value where eq 1 is valid and Kurdjumov and Maksimova's observations could have been made, to a somewhat smaller value, less than the zero-point energy, where eq 1 may be invalid and the growth process could take on more of the characteristics of sound-wave propagation.

In order to check this hypothesis, it is necessary, among other things, to repeat the work of Kurdjumov and Maksimova, whose observations have not been reproduced yet despite earnest attempts by the authors. Although it is possible that Kurdjumov and Maksimova were mistaken in their observations, it is more probable that their published alloy compositions are in error, or that a misunderstanding of some sort exists concerning their procedure. These possibilities are being examined in a series of experiments being undertaken in our laboratory.

**C. Crussard** (*Ecole des Mines, Paris, France*)—The fact that martensite is formed at temperatures as low as  $4^\circ\text{K}$  is extremely interesting in itself; but in its interpretation there is need for care. At first glance, it seems to substantiate the theory of athermal nucleation of martensite, as no activation seems possible at absolute zero. But this conclusion is incorrect, because the theory of thermal motion generally accepted for solids is incorrect. I have shown elsewhere<sup>17</sup> that for transformation involving a simultaneous displacement of several atoms, the Boltzmann formula does not apply; the correct theory must take in account the interferences of thermal waves. A rough hypothesis has led me first to a formula of the type:

$$P \approx e^{-\sqrt{A/\epsilon}} \quad [2]$$

where  $P$  is the probability of activation,  $A$  an energy involving the shape of the nucleus, and  $\epsilon$  the expression of the energy for a mode of vibration:

$$\epsilon = h\nu \frac{1}{2} + \frac{1}{e^{h\nu/kT} - 1} \quad [3]$$

The active frequency,  $\nu$ , depends also on the size of the nucleus; it is never far from the cutoff frequency.

A better, but still approximate calculation (to be published) leads to a more satisfying formula:

$$P \approx e^{-\frac{A}{\epsilon}} \quad [4]$$

The formula holds also for single atoms.

Thus, activation is possible even at absolute zero (another possibility being the "tunnel effect" for electrons). The departure between the Boltzmann formula and the eq 4 is very difficult to test by experiment. Martensite transformation seems the best example. The author's experiments can be explained by eq 4, if it is assumed that martensite nucleates at quenching temperature.

The athermal nucleation theory, assuming martensite embryos to be formed at austenitizing temperature, actually meets very great difficulties:

1—If it is assumed that the embryos are produced by local fluctuations in composition of the alloy, the size-distribution curve of embryos is independent of temperature; thus stabilization of austenite cannot be explained. Moreover, the reverse transformation cannot be explained easily.

2—If it is assumed that the embryo is of the dislocation type, all the experimental facts do rather prove that dislocations stabilize austenite: On the other hand,  $M_s$  should strongly depend on the state of polygonization of austenite, a fact which has not yet been observed, to my knowledge.

It seems easier to explain stabilization of austenite by some kind of hardening in the austenite itself (some new experiments in my laboratory point to that result), which increases the stress-energy barrier to the transformation, because martensite cannot be formed without some kind of plastic deformation in the platelet or in the surroundings. Thus, there is no reason to reject the theory by which martensite is formed at quenching temperature, as is assumed by Scheil and others, according to the detailed mechanism of grouping of thermal waves which I proposed.<sup>18</sup>

**N. A. Ziegler and P. H. Brace** (*Crane Co., Chicago*)—This very interesting paper, and particularly that part of it which deals with subzero transformations in 18-8 type steels, illustrates and rationalizes some of our observations.<sup>19</sup>

One of the present discussers as early as February 1947 discovered that Charpy bars, made of certain austenitic stainless steel compositions, after having been fractured at the temperature of liquid nitrogen (about  $-300^\circ\text{F}$  or  $-185^\circ\text{C}$ ), became, adjacent to the fracture, rather strongly magnetic. This increased magnetic permeability persisted at room temperature and apparently was caused by an (at least partial) transformation of the austenitic phase into ferritic.

This supposition was substantiated by hardness measurements taken close to the fracture ("magnetic" region), as compared to those taken away from the fracture ("nonmagnetic" region). The "near-fracture" hardness, at least in some cases, increased to values seldom observed in conventionally cold-worked steels of this type. Likewise, microexamination of "near fracture" regions disclosed structures very similar to that shown by the authors' Fig. 2b. None of these phenomena could be observed in the bars of similar compositions, but fractured at room temperature. Nor could they be produced in samples plastically deformed at room temperature and then cooled to the temperature of liquid nitrogen.

Briefly, it was demonstrated that this  $\gamma$  to  $\alpha$  transformation was promoted by a simultaneous application of plastic deformation and low temperature and could not be produced by these two factors applied separately.

Subsequent and more elaborate experiments established that compositional range, in the family of Fe-Cr-Ni alloys, which responds to the mechanical working at subzero temperatures. Roughly, it can be defined on the triaxial diagram by the following points: 18 pct Cr-4 pct Ni, 12 pct Cr-20 pct Ni, and 30 pct Cr-14 pct Ni.

However, in order to develop this effect to its maximum, these steels have to be thus worked to about 70 pct reduction of the original cross-sectional area. This was demonstrated by rolling and wire-drawing experiments, each performed in several consecutive steps of simultaneous chilling and plastic deformation. Even though this hardening effect can be achieved at temperatures as high as  $-100^\circ\text{F}$  ( $-73^\circ\text{C}$ ), for practical reasons chilling in liquid nitrogen was found to be more convenient.

Moreover, it also was found that such steels, plastically deformed at a subzero temperature, can be made still harder by aging them at about  $750^\circ\text{F}$  ( $400^\circ\text{C}$ ).

Other physical properties are affected in the same proportion as hardness, so that in an 18-8 strip rolled at  $-300^\circ\text{F}$  ( $-185^\circ\text{C}$ ) and aged at  $750^\circ\text{F}$  ( $400^\circ\text{C}$ ) the following values can be obtained: tensile strength, 295,000 psi; yield stress, 290,000 psi; proportional limit, 264,000 psi; elongation, 2.0 pct; reduction of area, 24.8 pct; and hardness, 607 V.P.N. More recently, hardness values of well over 700 V.P.N. have been obtained.

Some preliminary experiments have shown the possibility of a considerable improvement in the wear resistance of austenitic Cr-Ni steels. Likewise, some exploratory tests indicate that the salt-water corrosion resistance of samples thus treated is not greatly affected by the special hardening process described.

In a word, it appears that the phenomenon of martensite formation in austenitic stainless steels, so ably described by Kulin and Cohen, might have valuable practical applications.

**S. A. Kulin and M. Cohen** (authors' reply)—The discussion submitted by Drs. Fisher, Hollomon, and Turnbull is most ingenious, and warrants careful consideration because it points up the very issue that this paper seeks to settle. Of course, it is true that the Boltzmann equation may lead to serious discrepancies at temperatures approaching absolute zero. However, we used the equation only because it is a consequence of the atom-by-atom mechanism of growth which the discussers have postulated, and we wished to test the predictions of this mechanism in a critical way.

In the light of the present paper, Drs. Fisher, Hollomon, and Turnbull suggest that the Boltzmann equation may still be applicable to the martensite transformation for alloys in which the activation energy for growth is larger than the zero-point energy of the lattice ( $\sim 1000$  cal per mol), a possible example being the 0.6 pct C, 6 pct Mn steel of Kurdjumov and Maksimova who reported an activation energy of 1600 cal per mol. However, in the case of the alloys studied in the present investigation, the discussers propose that the activation energy may be less than the zero-point energy and hence the growth may "take on more of the characteristics of sound-wave propagation."

The above distinction appears questionable in view of the following. A 0.6 pct C, 8 pct Mn steel was strained at 4°K, and the martensite content increased from about 90 pct (the amount formed on straight cooling) to about 99 pct during the brief straining period. If the available 10 pct austenite were retained because of a slow atom-by-atom diffusion process, it could not be induced to transform appreciably at 4°K within the few seconds of straining. Furthermore, Kurdjumov and Maksimova<sup>20</sup> have recently reported an activation energy of only 600 cal per mol for a ferrous alloy of 23 pct Ni, 3.4 pct Mn. Notwithstanding this low activation energy, the indications are that the transformation characteristics at low temperatures are quite similar to those of the 0.6 pct C, 6 pct Mn alloy.

These findings indicate that there is considerable doubt concerning the significance of the 1600 and 600 cal per mol values as activation energies for martensitic growth. Other interpretations are possible; for example, Kurdjumov and Maksimova regard these values as the activation energies for nucleation. Thus, the reaction may be controlled by the availability of

nuclei rather than by the rate of atomic diffusion. This question will be dealt with by E. S. Machlin in a forthcoming paper on isothermal martensite formation.

Professor Crussard points out some of the difficulties in the athermal embryo theory of martensite nucleation and presents arguments in favor of isothermal nucleation due to the grouping of thermal waves. Actually there is now strong experimental evidence contrary to both of these viewpoints and in favor of the strain embryo concept. The case against isothermal nucleation resulting from thermal fluctuations or waves is indicated by the following experiment conducted by E. S. Machlin. If the isothermal transformation in a 70 pct Fe, 30 pct Ni alloy at  $-70^{\circ}\text{C}$  is interrupted by heating briefly to about  $60^{\circ}\text{C}$ , the subsequent transformation at  $-70^{\circ}\text{C}$  is almost completely inhibited. On the other hand, if the holding at  $60^{\circ}\text{C}$  is conducted before the first cooling to  $-70^{\circ}\text{C}$ , there is no effect on the isothermal transformation at  $-70^{\circ}\text{C}$ . In both instances, the thermal fluctuations or waves at  $-70^{\circ}\text{C}$  are the same, but the isothermal reaction depends on the state of strain due to the martensite formed on cooling. If relaxation is allowed to take place, the isothermal transformation is reduced in magnitude. In other words, the nucleation of isothermal martensite does not result from thermal vibrations alone, but from their superimposition upon existing strains which are produced, for the most part, by the martensite formed during cooling.

Recent experiments on the effect of plastic deformation substantiate the strain embryo theory of martensite nucleation. Plastic deformation of single crystals raises  $M_s$ , and slip lines do not stabilize the austenite. The same tendency exists in polycrystalline alloys, but the effect may be obscured because the nonhomogeneous deformation partitions the austenite and causes the martensite to form in smaller units.

The remarkable strengthening of austenitic stainless steel by deformation at subzero temperatures, as described by Drs. Brace and Ziegler, is a striking application of the principles of martensite formation. This unusual type of metal processing has commercial potentialities and its effective utilization will be watched with interest.

## The Isothermal Transformation of a Eutectoid Beryllium Bronze

by Ronald H. Fillnow and David J. Mack

### DISCUSSION, A. R. Troiano presiding

**R. Haynes** (*University of Sheffield, Sheffield, England*)—The authors have presented some interesting data on the isothermal transformations of 6 pct Be-Cu. The reactions are extremely interesting for they appear to show a type of reaction which has not been noted before. The previously accepted temperature of the eutectoid is surprising in view of the relatively rapid rates of transformation observed in these experiments.

The growth of coarse eutectoid from fine eutectoid is an unusual phenomena, since on quenching to room temperature the phases present before and after the reaction appear to be the same. This reaction is attributed to recrystallization of  $\alpha$ . Recrystallization usually is associated with the release of strain energy from a deformed lattice. It seems to be unlikely that sufficient strain will be imparted to the lattices of the

products of transformation at the high temperatures to provide sufficient energy for a recrystallization process, neither will sufficient energy result from the decrease in interfacial area between the two phases. One would expect that strains will be dissipated almost as soon as they are set up due to the plastic condition of the metal at the high temperature. It is difficult to conceive the recrystallization of one phase affecting the distribution of a second phase with which it is associated.

Consider the formation of a lamellar eutectoid from a solid solution. The conditions may be represented by Fig. 34, the lamellae lying in a direction at right angles to the plane of the paper. The growth of such an aggregate is edgewise, as is expected from theoretical considerations.<sup>10</sup> If we assume that the shaded lamellae are representing the  $\gamma$  phase in copper beryllium and the unshaded the  $\alpha$  phase, which are growing through the  $\beta$

Fig. 34 (left)—Mechanism of growth of eutectoid lamellae.

Figs. 35 (center) and 36 (right)—Hypothetical mechanisms of growth of eutectoid lamellae from finer eutectoid lamellae.

phase, then immediately in front of the advancing lamellae, the beryllium atoms in the  $\beta$  phase would be expected to diffuse towards the  $\gamma$  plates, while copper atoms will tend to diffuse towards the  $\alpha$  plates. Consider now the growth of coarse lamellae of  $\alpha$  and  $\gamma$  through finer lamellae of  $\alpha$  and  $\gamma$ . The conditions are as shown in Figs. 35 and 36. For the coarse lamellae in Fig. 35 to grow, it is necessary that diffusion should occur in the thin lamella of  $\gamma$  phase, or  $\alpha$  phase, as the case may be. This implies that in part of the  $\gamma$  lamella some of the beryllium content must diffuse away until formation of the  $\alpha$  phase occurs, or in the case of an  $\alpha$  lamella, the beryllium content must be increased by diffusion until  $\gamma$  phase is formed in certain areas. Similar difficulties are met in the case of Fig. 36, since diffusion, as indicated, would result in the alloy going from a more stable to a less stable condition. This is contrary to thermodynamics and to previous observations. It might well be asked, where does the constraint which initiates such diffusion come from? On this assumption it may be expected that coarse eutectoid will grow through coarse eutectoid, yet this is not observed. It is suggested, therefore, that at the temperature of reaction the fine eutectoid structure observed is not composed of the  $\alpha$  and  $\gamma$  phases but of some intermediate phase, or phases, which break down to  $\alpha$  and  $\gamma$  during quenching. Such a phase could give a coarse structure isothermally, while not precluding the possibility of the  $\beta$  phase breaking down directly into the coarse structure. One wonders if there is more in the lamellar appearance of the  $\beta$  phase noted at 500°C than has been assumed. By analogy one is reminded of the formation of eutectoid from both  $\beta$  and  $\beta_1$  in eutectoid copper aluminum, although the analogy should be treated with caution. Thus two paths seem to be possible for the decomposition, i.e.  $\beta$  to fine eutectoid to coarse eutectoid, and  $\beta$  to coarse eutectoid. It would be interesting to know if after quenching to room temperature the fine eutectoid will continue to form coarse eutectoid when replaced in the isothermal bath.

Klier and Grymko<sup>3</sup> indicated in their paper that the interlamellar spacing of the eutectoid aluminum bronze behaved in an anomalous manner: First decreasing and then increasing as the transformation temperature was lowered. This has been confirmed in a quantitative

Fig. 37 (right)—Authors' Fig. 19 plus additional data.

manner. Do the interlamellar spacings of the fine and coarse eutectoids show a similar behavior?

It would be interesting to learn if any relationship exists between the lamellae of the fine and coarse eutectoids.

It has been observed in eutectoid copper aluminum alloy isothermally transformed to eutectoid below the  $M_s$  temperature that pseudomorphs of the martensitic structure can be seen, so that pseudomorphs of the fine eutectoid in the coarse eutectoid do not seem to be evidence for the phases present in the fine eutectoid being  $\alpha$  and  $\gamma$ .

At the lower temperatures it has been observed that a metastable precipitate forms early in the reaction and then quickly disappears and is followed by the "ripple" structure. The product of such a reaction cannot be  $\beta$ . Would it not be better to designate it by  $\beta'$  or some other symbol? The ripple structure then takes on a mottled appearance. This is similar in appearance to the latter stage of the  $\beta$  to  $\beta_1$  reaction in eutectoid copper aluminum. May not the reaction be analogous?

There seems to be little justification for the use of two hardness scales on the hardness-transformation-time diagrams. Even in a single phase alloy the results are not directly comparable. On a multiphase alloy one wonders if any simple correlation can exist. The use of microhardness for following isothermal reactions seems to be open to question. Such a method must result in the hardness of only one of the many constituents being determined by any one impression, with the result that for a number of impressions which are randomly distributed the hardness of a partially transformed specimen will vary over a very wide range. This difficulty can be overcome by the use of a large indenter, say a 10 mm Brinell ball: This is not possible if small specimens are to be used, or by taking numerous hardness impressions and computing a mean value. The claim that the microhardness data correlates well with observed microstructures seems rather sweeping. In Fig. 30, for example, the results appear to show a scatter of 100 points pyramid for a structure which does not change greatly with time. Fig. 19 shows a number of undulations in the curve. On examination of the curve it might be concluded that points (3) and (4) (my reference marks in Fig. 37) were of significance. This is not so. It is possible to draw a fairly smooth curve, as shown, for the results from 500°C downwards. This, however, results in the elimination of the "significant" change in direction at (2). To a lesser extent this criticism can be levelled at most of the hardness curves. One concludes that the use of microhardness, by itself, is completely unsuitable for following the reactions, and that the various "start" and "finish" times on the curves are derived from microscopical evidence.

Confirmation of the microscopical results is made by the X-ray diffraction method. By examination of the photographs in the cases of coarse and fine eutectoid, it can be seen that at high angles of reflection the doublet  $\alpha$  of the  $K_\alpha$  radiation appears to be resolved, while in the case of the slowly cooled alloy the ring is blurred. In a quenched alloy the rings are expected to be blurred and the doublets unresolved at high angles. This is borne out by quenched specimens of the eutectoid Cu-Al alloy. One is led to wonder how efficient was the quench, or if the specimens have received a stress relieving anneal? If so, it is not possible that changes may have occurred.

**J. E. DeMoss** (University of Notre Dame, Notre Dame, Ind.)—I have been working on the transformations of the  $\beta$  phase in the Be-Cu system for some time and, hence, particularly appreciate the peculiarities and complexities which confronted the authors.

From my results, I agree with the authors that the accepted eutectoid horizontal temperature is too low and that actually it is somewhat above 600°C. This has been pointed out by Thomas.<sup>11</sup>

My results on the isothermal transformation of a eutectoid Be-Cu alloy are in essential agreement with those of the authors. I have observed many of the

"unusual microstructures" which have been shown in this paper including the initial appearance of fine pearlite and its ultimate replacement by coarse pearlite. However, I find it difficult to accept that the coarse pearlite forms from the fine pearlite by a nucleation and growth process, although that may appear to be the mechanism.

Evidently the  $\beta$  grain size of the authors' alloy must have been reasonably small. I have observed that the time for completion of the isothermal reaction is quite long, even at 500°C, when the  $\beta$  grain size is of the order of 1.5 mm average grain diameter. The time for the beginning of the reaction, though, seems affected very little by the  $\beta$  grain size. The writer has found that it is possible to refine the  $\beta$  grain size only by cold working the slowly cooled alloy after it has transformed to  $\alpha$  plus  $\gamma$  and reheating to the  $\beta$ -phase field. Heating through the allotropic transformation, as in steel, seems to have no effect on the  $\beta$  grain size. Do the authors have any information on this point?

I cannot agree with the authors' statement in point 5 of the summary that "Even though the cooling of the specimen is interrupted by an isothermal holding at an intermediate temperature, the remaining beta can also be retained at room temperature by the subsequent quench." I have isothermally transformed a eutectoid specimen at 300°C for 1 hr and obtained no microscopic evidence of transformation. The specimen appeared to be all  $\beta$ , yet the X-ray diffraction pattern showed only  $\alpha$  and  $\gamma$  lines and no  $\beta$ . I also have obtained X-ray evidence that a quenched eutectoid  $\beta$  undergoes transformation on remaining at room temperature. I can cite many more very interesting and confusing X-ray results on this alloy, but my point is that the transformations of the  $\beta$  phase in the Be-Cu system are far from simple, and that what appears to be  $\beta$  may not always be  $\beta$ .

**J. T. Richards** (*Beryllium Corp., Reading, Pa.*)—The authors of this excellent work have identified three isothermal transformation products: Fine pearlite, coarse pearlite, and  $\beta$ . There is no indication, however, as to the structure in which the microhardness determination was made. It would have been of interest if microhardness curves had been plotted for each structure at the transformation temperatures producing more than one structure.

Although Raynor<sup>12</sup> has given the eutectoid temperature as 575°C based on four prior investigations, there is considerable evidence to substantiate the authors' claim that this value is too low. Masing and Dahl<sup>13</sup> found by microscopic investigation that a 6 pct Be-containing alloy was still homogeneous after quenching from 620°C, although there are indications of incipient decomposition. On the basis of microscopic and hardness tests by Ewing<sup>14</sup> the eutectoid temperature falls between 600° and 620°C. Borchers and Otto<sup>15</sup> claim that the eutectoid temperature may run as high as 50°C over the generally accepted figure (575°C), based on a dilatometric investigation with a maximum heating rate of 0.65°C per min.

Perhaps one of the most complete studies of the eutectoid transformation was conducted by Thomas.<sup>16</sup> From dilatometric investigations, an average of 620°C was obtained on heating at 0.5 to 1.0°C per min, while cooling at 1°C per min gave 601°C. Electrical resistance measurements on heating yielded 618°C. These results were checked by thermal analysis and values of 618°C (on heating at 4°C per min) and 601°C (on cooling at 5°C per min) were obtained. Thomas claims that the low values previously reported result from dilatometric curves being taken only for decreasing temperatures and at too rapid cooling rates.

In considering the above results together with those of the present authors (608°C), a range of 608° to 610°C is suggested for the eutectoid temperature instead of the accepted figure of 575°C.

There is good agreement on the hardness of the various structures between Ewing<sup>14</sup> and the present paper. For specimens quenched from 700° to 800°C,

Fig. 38—Changes in hardness at 400°C.

Ewing obtained Vickers hardnesses ranging from 561 to 614 for the  $\beta$  phase, while the present authors give values from approximately 550 to 640. Ewing reports a hardness of 243 for a specimen heated at 570°C for 2½ hr, comparing with an approximate value of 245 in the present paper for the same time at an isothermal transformation at 550°C. As a matter of interest, Ewing found that the hardness of 243 obtained by heating for 2½ hr at 570°C increased to 566 upon further heating for 15 min at 620°C.

Although Ewing did not employ isothermal heating, his results obtained by quenching to room temperature followed by reheating give the same general trend. Fig. 38 superimposes one of Ewing's curves on the authors' Fig. 23.

**R. H. Fillnow and D. J. Mack** (authors' reply)—The writers wish to thank Messrs. Haynes, De Moss, and Richards for the additional information they have contributed. All results indicate that the currently accepted eutectoid temperature must be revised upwards to about 610°C.

The authors have repeatedly observed what Professor De Moss points out, i.e., that the  $\beta$  grain size in this alloy cannot be refined by simple heating through the transformation range, as is the case with steel. This phenomenon is well known in aluminum bronzes and is apparently the customary behavior in eutectoid transformations where neither component exhibits allotropy. Thus there are two types of eutectoid transformation as Harrington<sup>17</sup> has pointed out: The allotropic eutectoid and the plain eutectoid.

Unfortunately, the authors' X-ray diffraction studies were confined to the lamellar  $\alpha$  plus  $\gamma$  aggregates and hence we cannot comment on Professor De Moss' results regarding the transformation of  $\beta$  to  $\alpha$  and  $\gamma$  without change in microstructure. Such a transformation is certainly possible and may be associated with some of the transitory changes in microstructure that occur. We are in complete agreement with Professor De Moss concerning the complexity of the transformations in this system.

Professor Haynes has pointed out the objections to the simple mechanism proposed by the authors for the two pearlite reactions. The possibility of the fine pearlite being composed of metastable phases, say  $\alpha'$  and  $\gamma'$ , should not be ruled out until more definitive experiments have been performed. However, one need not rule out recrystallization of the  $\alpha$  because of strain energy requirements and the apparently logical assumption that at high temperatures this strain energy would be released by localized plastic flow for the following reasons:

1—"Recrystallization" of  $\alpha$  in an alloy containing 1.92 pct Be has been observed at 400°C.<sup>5</sup> Here the mechanism is a solution and redeposition of the precipitate at the advancing interface. The appearance

of the coarse pearlite suggests this mechanism of discontinuous precipitation.

2—Release of the strain energy might not be possible because of the rigidity of the lattice caused by its high solute metal content and the restraint imposed on the  $\alpha$  by the adjacent lamellae of  $\gamma$ . As a matter of fact, experiments now underway on the Cu-Sb eutectoid have shown that a quench of the high temperature body-centered tetragonal  $\beta$  phase into a salt bath held only 20° below the eutectoid temperature (436°) results in strain markings due to anisotropic contraction of the tetragonal phase. These strain markings later serve as sites for the precipitation of the stable end product phases.

It is believed that the apparently diverse views of Professor Haynes and the writers will coincide if the existence of metastable  $\alpha'$  and  $\gamma'$  or some transition lattice can be established, because there will then be an easy energy path for the reaction to follow.

No quantitative measurements have been made on the lamellae of either the coarse or fine pearlite. Both get finer as the transformation temperature is lowered, but no coarsening was observed below the nose of the transformation curves.

In answer to Professor Haynes' objection to the use of microhardness methods, the authors found that a very light load was necessary for obtaining hardness values of the retained  $\beta$ . With the heavier loads used, for example, with a Rockwell C scale, the indenter had a tendency to shatter the brittle  $\beta$ . For the sake of uniformity of data, microhardness determinations were used throughout.

The authors must remind Professor Haynes that microhardness determinations were not used to fol-

low the isothermal reactions. Any start or finish times, as given on the various hardness curves, were obtained solely through metallographic methods. Hardness data was obtained only for purposes of a qualitative correlation with metallographic data. Since this was the purpose of the hardness readings, several traverses were made across the specimen if two phases existed, and a mean value taken. In answer to Mr. Richards, this gave a very acceptable, reproducible hardness value. The variation in hardness values, shown on Fig. 30, was the largest spread found throughout the work. Approximately 90 pct of the hardness values obtained by the traverse method had a spread of only 10 or 20 points on the Vickers scale. The Rockwell scale was placed on the hardness plots in addition to the Vickers hardness scale only as a guide for those readers unfamiliar with the Vickers hardness numbers.

## The Effect of Alloying Elements on the Plastic Properties of Aluminum Alloys

by J. E. Dorn, P. Pietrokowsky, and T. E. Tietz

DISCUSSION, R. M. Parke presiding

**A. I. Snow** (University of Chicago, Chicago)—In a footnote to their paper the authors cite the work of Ageev and Guseva on the distribution of the electronic density in aluminum and quote from *Chemical Abstracts* that: "Comparison between the experimental (structure factor) curves and the theoretical curves drawn for  $Al^{+}$  and  $Al^{+++}$  leads to the conclusion that in the metal crystal lattice, Al is present as approximately bivalent ions." The words in parentheses, "structure factor", which are evidently inserted by Dorn and coauthors, are misleading since what was compared were not structure factor curves but electron density curves, namely, the ones obtained by using the structure factors as coefficients in a three dimensional Fourier series compared with electron densities calculated for various assumed valence states. In a later paper Ageev and Ageeva use intensity data obtained by themselves, instead of from the literature as in the first paper, and this time arrive at a valence for metallic aluminum of approximately 2.5. The results of both papers by Ageev and coauthors concerning the valence of aluminum are open to serious question

since it has been shown theoretically<sup>25</sup> that no matter whether aluminum is mono-, di- or trivalent the atomic scattering factor curves in the range of observable X-ray diffraction maxima are identical. These atomic scattering factor curves only differ appreciably below the value of  $\sin \theta/\lambda$  of the first reflection that it is possible to observe (111). Therefore the structure factors and intensities of a given reflection will be identical for all three possible valence states and the use of the experimentally determined structure factors will lead to no knowledge of the valence states of aluminum no matter how mathematically manipulated. There are other serious objections to the treatment of the experimental data by Ageev and coauthors in these and other papers which I intend to discuss elsewhere.

**J. E. Dorn, P. Pietrokowsky, and T. E. Tietz** (authors' reply)—We wish to thank Dr. Snow for his interpretation of the results obtained by Ageev and Guseva on the electron density curves in metallic aluminum. They are looking forward with interest to Dr. Snow's paper on this subject.

<sup>25</sup> R. W. James: *The Optical Principles of the Diffraction of X-rays*. p. 303. (1948) London. G. Bell and Sons, Ltd. James points out the difficulty in obtaining the valence of aluminum by comparison of calculated and experimentally obtained atomic scattering factor curves but does not point out that this must also necessarily entail difficulty in obtaining valence values from electron density curves.

## The Properties of Some Magnesium-Lithium Alloys Containing Aluminum and Zinc

by Robert S. Busk, Donald L. Leman, and John J. Casey

DISCUSSION, R. M. Parke presiding

**P. D. Frost** (Battelle Memorial Institute, Columbus, Ohio)—I would like to comment on the statement on p. 946 of the paper, in which the authors say that increasing lithium increases stability. This is somewhat misleading. Refer, for example, to the 6 pct Al alloy in

Table III. Increasing the lithium from 3 to 12.5 pct results in a high strength alloy. This alloy attains its maximum yield strength in the quenched condition; subsequent aging at 180°F effects softening. When the lithium content is increased to 16 pct, an alloy is produced which has lower strength as quenched, but whose aging cycle at 180°F is somewhat slower than that of the Mg-12.5 pct Li-6 pct Al alloy. Thus, this alloy undoubtedly attains its maximum strength after aging a few hours at 180°F.

If aging were carried out for a much longer period

than 16 hr, it would be observed that the final strength, for a given aluminum content, would be higher as the lithium was decreased. This is demonstrated for an 8 pct Al alloy in Fig. 4. The alloy having 13.1 pct Li attains maximum hardness as quenched from 700°F. Increasing the lithium to 15.3 pct delays the aging cycle slightly, and the peak hardness occurs after about 1 hr at 200°F. The stability, however, is actually lowered.

When the lithium level is lowered to 8.8 pct, the hardness, as quenched, is lower. However, the aging curve is considerably flatter, and the hardness after 1000 hr at 200°F is higher than either of the higher lithium alloys.

**D. L. Leman** (authors' reply)—Mr. Frost's data on the extended aging of Mg-Li-Al alloys is an important contribution to this paper and is appreciated. However, it was not our contention that increasing lithium increases stability of properties over the entire range of lithium studied. This statement was made on the basis of alloys containing 12 and 16 pct Li, both of which have a wholly cubic structure. The exceptional high strength properties obtained in this alloy system are possible only with the predominately cubic alloys. The subsequent major loss of strength is associated with the high strengths produced. Alloys which have a predominately hexagonal crystal structure are definitely more stable than the cubic alloys but at a lower strength level as shown in Table III.

We also believe that the statement regarding the

Fig. 4—Effect of lithium on aging Mg-Li-Al alloys.

effect of lithium content on property stability is applicable. High strength is produced by precipitation hardening and the question of stability is therefore dependent on the tendency of the alloy to overage rather than on its strength in the overaged condition. It is not uncommon for the strengths of age-hardenable alloys in other systems to equalize in the overaged condition even though the aging curves may differ considerably. The superiority of Mg-16 pct Li-10 pct Al over Mg-12.5 pct Li-10 pct Al (or Mg-15.3 pct Li-8 pct Al over Mg-13.1 pct Li-8 pct Al) in this respect is significant and would be expected to be even greater as the temperature of exposure is lowered.

## The Effect of Sodium Contamination on Magnesium-Lithium Base Alloys

by P. D. Frost, J. H. Jackson, A. C. Loonam, and C. H. Lorig

DISCUSSION, R. M. Parke presiding

**R. J. M. Payne and J. D. L. Eynon** (*J. Stone and Co. Ltd., Deptford, London, England*)—We at Deptford have worked on Mg-Li alloys since May 1947. It is hoped that a formal paper which will be largely concerned with the effects of impurities will be presented to the Institute of Metals (London) in the near future. Pending its publication we offer the following comments on this paper.

As the authors observe, the preparation of satisfactory Mg-Li alloys is largely a matter of securing freedom to a sufficient degree from the other alkali metals which are so often found in association with the basic metals. We too started with the LiCl-KCl flux and impure lithium, we changed to fluxes composed wholly of lithium salts, we refined our lithium by vacuum fusion until such time as the high grade lithium became available, we grew more watchful for impurities and became increasingly critical of our raw materials (including the magnesium) as the work proceeded. In our investigations we were greatly handicapped by the lack of reliable analyses, and it is only recently, and as a result of much careful work, that methods for determining the very small amounts of sodium and potassium, which we now know to be significant in alloys, have become available. Investigations carried out at the Admiralty Materials Laboratory, Holton Heath, Dorset, England, have put analytical procedures on a firm footing and we feel that we can now speak with confidence regarding the amounts of alkali metals which can be tolerated in the final alloys: We can also give tolerance limits for impurities in basic metals and salts. We agree that the principal difficulty in working with Mg-Li alloys is with sodium. As we see it, the main concern of the present authors has been to secure the full ductility of the material in the cast or wrought condition and to this end they have found it advantageous to reduce sodium contents to a low level. We have discovered a further reason for excluding sodium from melts of Mg-Li alloy and one which necessitates that the amount of this element be held at an even lower level. We have found that while alloys containing about 0.01 pct Na may in the cast condition show the full ductility

of which the material is capable, such alloys may be unstable and liable to develop intergranular weakness due to the precipitation of sodium. We have evidence that there is a very marked difference in the solubility of sodium in the  $\beta$  phase between temperatures of about 400°C and room temperature, and that alloys which were ductile as-chill-cast or as-wrought may embrittle very seriously on mild heating or even on standing at room temperature. To avoid these effects we consider it desirable to limit sodium to much smaller contents than those which just permit good elongation to be obtained in the cast or wrought state. The degree to which complex alloys are affected by sodium depends on the particular elements added to the basic Mg-Li alloy. From our own work we have seen that the sensitivity to sodium is considerably less marked in wrought than in cast alloys, and it may be for this reason that Frost and his colleagues have found as much as 0.03 pct Na unobjectionable in an alloy containing 9 pct Li and 4 pct Zn (Fig. 1): It is possible under certain conditions of heat treatment that this same alloy would have developed intergranular weakness through the precipitation of sodium. A difference in the sensitivity to sodium as between wrought and cast products would be understandable in view of differences in grain size: For an alloy of given sodium content, the concentration of sodium at the boundaries will obviously be less in the case of a fine grained material due to the greater area over which the impurity is spread. A tendency for sodium to seek grain boundaries has already been reported by Busk, Leman, and Casey.<sup>1</sup> These authors, however, refer specifically to ternary Mg-Li-Al and Mg-Li-Zn alloys and have not apparently realized that the same phenomena may be met in basic binary compositions. So far we have seen no report of solubility varying with temperature. We have made a conclusive demonstration of the solubility of sodium by heating to 400°C and quenching an alloy containing sufficient sodium as to cause it to break with zero elongation when tested as chill cast: The specimen thus heat treated was quite ductile.

We have spent much time, as have the American workers, in seeking methods of eliminating sodium

from melts, thus removing the need for very high purity in basic materials; success in this field has, however, been limited. We do not propose to pursue this topic at any length, but will record that we do not find the LiCl-LiF flux to have outstanding virtues as regards sodium removal; in fact we regard it as inferior to simple LiCl in this respect. We are aware that the chloride-fluoride flux has other advantages which make it preferable to the simple chloride in certain circumstances.

**H. M. Skelly** (*Aluminum Laboratories Ltd., Kingston, Ont., Canada*)—Have any tests been made for flux inclusions in melts of Mg-Li alloys prepared under a covering flux of 75 pct LiCl plus 25 pct LiF?

**P. D. Frost, J. H. Jackson, A. C. Loonam, and C. H. Lorig** (authors' reply)—It was a pleasure to receive the excellent discussion from Messrs. Payne and Eynon. The observation regarding the difference in solubility of sodium between 400° and 20°C is very interesting and may account for some of the hardness changes we have obtained in aging quenched binary alloys.

Most of our work has been with wrought alloys. It has been our experience that cast Mg-Li ingots must be hot worked considerably to develop good properties. The precipitation of sodium at the boundaries of coarse grains undoubtedly contributes to low ductility in castings. Of course, a wrought, fine grained structure usually has greater ductility than a cast structure, even in the absence of contaminating elements.

It is noteworthy that Messrs. Payne and Eynon found that LiCl removed sodium more effectively than the LiCl-LiF flux. We found that the LiCl-LiF flux was very effective. However, we believe that the efficiency of these various salt mixtures depends to a major extent on the sodium content of the salt as procured.

In reply to Dr. Skelly, fracture tests on cast ingots and wrought specimens rarely reveal flux inclusions in Mg-Li alloys. On the other hand, the alloys often become badly pitted under humid conditions. We are, at the present time, attempting to evaluate the effect of contaminating materials, such as flux, on corrosion resistance.

## Hydrogen Embrittlement of SAE 1020 Steel

by J. B. Seabrook, N. J. Grant, and Dennis Carney

*DISCUSSION, R. M. Parke presiding*

**G. A. Moore** (*University of Pennsylvania, Pittsburgh*)

—The authors are to be congratulated for making several very important additions to our information on the nature of hydrogen embrittlement. While it is pleasing that the relation of ductility to hydrogen content has been so closely checked with our previous work,<sup>10</sup> the agreement is perhaps more fortuitous than realized, since steels of quite different carbon content and structure are compared. The agreement emphasizes that the embrittling effect is mainly on the ferrite phase, while cases of disagreement, such as the occurrence of "permanent damage," re-emphasize the fact that hydrogen tends to be highly segregated, so that its effects must be more localized (microscopically) in the cast material than in these electrolytically charged cases. The hydrogen content to cause actual microcracks and thus decrease impact values, therefore, varies widely with structure and source of hydrogen.

A great advance has been made by the inclusion of the natural stress-strain data in the present paper. At the time of the earlier report, we did not realize the fallacy of using the metallurgically meaningless engineering values until too late to obtain the complete data, an omission which I have personally had numerous occasions to regret. Approximate determinations of the fracture stress did show a better correlation to hydrogen than the ductility measurements, but the lack of the stress-strain curves prevented a complete analysis of the effects occurring. The authors would be justified in discussing Fig. 5 in much greater length. The figure appears to justify analysis as follows:

The conclusion of Smith<sup>8</sup> that none of the hydrogen is in actual solution in the lattice is supported by the lack of hydrogen effect on the yield strength and hardness. The conclusion that after slight strain the hydrogen is occluded in rifts, mosaic disjunctions, or the tension sides of Taylor dislocations, and spreads these openings, is supported by the fact that the effect on the flow curve could be expressed as the addition, without dimensional change, of a plastic strain of 0.05 to 0.10, in line with earlier statements that "the effect of hydrogen is similar to that of a little cold working." This mode of occlusion is realized to induce tensile microstresses, largely triaxial, in the noninterrupted portions of the lattice structure, which stresses tend to interfere with flow. These stresses now may be

estimated for the first time from the information that the flow stress of charged bars lies about 6000 psi above that of uncharged bars. Presuming the actual value of the critical shear stress unaffected by hydrogen, then in the presence of a radial biaxial tension, either the maximum or octahedral shear stress laws require that the applied tensile stress be increased by the same amount to maintain flow. Thus the microstresses induced by the hydrogen here have a net unbalanced radial component averaging about 6000 psi, except at the immediate surface where they are noted to have been relieved by blistering. The unknown triaxial component in the axial direction, which balances out in testing, may be added to obtain the actual microstress, but since the observed flow stress does not increase with further addition of hydrogen after about 2 ppm (or 0.2 relative volume), it is unlikely that the stresses ever actually exceed 10 pct of the estimated 100,000 psi calculated on the assumption that the volume occupied by the precipitated hydrogen is negligible.

The old argument as to whether the embrittlement is due directly to the presence of the rifts, or to the microstresses around the rifts, therefore appears resolved. The fracture stress is lowered progressively by continuing increases of hydrogen content, with an observed loss of 40,000 psi at contents of 5 to 10 ppm. The idea that the actual strength of the metal remains constant and the 40,000 psi stress is supplied by the gas pressure is incompatible with the small and fixed effect on the flow stress, hence it is clear that only a minor portion of the embrittling action is due to the stress, while a major portion is due to the extension of the rift system, with its interruption of the coherency of the metal and obvious notch effects.

As this analysis is of necessity based on the published figure alone, perhaps the authors will be so kind as to check it against the unpublished data and investigate other interesting details. For example, it appears that hydrogen reduces the amount of uniform strain just enough that the stress at maximum load is not changed, which may help explain how the hardness can be unchanged while the tensile strength rises, and perhaps also why some observers find hydrogen to lower the tensile strength, some to raise it, and many to find it to have no effect. Certainly the publication of more natural stress-strain data in connection with hydrogen embrittlement problems will be a very important addition to our understanding of the mechanism involved.

**J. B. Seabrook, N. J. Grant, and D. Carney** (authors' reply)—The authors thank Dr. Moore for his discussion and interesting analysis. It may turn out that the agreement as to minimum hydrogen required for maximum embrittlement is fortuitous. If the embrittling effect is truly mainly in the ferrite phase, however, it is conceivable that further experiments with the embrittlement of ferritic material will show agreement with the figure of 5 ppm at maximum embrittlement for the hot-rolled condition.

Because hydrogen segregates at the grain boundaries and interdendritic zones, it is expected that hydrogen will be much more segregated in cast materials, resulting in permanent damage. Accordingly, low values of hydrogen in a cast material need not signify freedom from damage, especially if the hydrogen has had an opportunity to diffuse out.

We hesitate to make specific far-reaching conclusions regarding all the information to be derived from the true tensile strength curves. We are not sure that one can express the differences in the flow curves as differences in strain; the effect may rather be looked upon as an increase in flow stress due to the occlusion of hydrogen shortly before the increase is measured. In this respect the effect of hydrogen would definitely not be "similar to a little cold work."

We agree that the difference in fracture stress of 40,000 psi is not supplied by gas pressure. High pressures can, however, be exerted. The surface bursts which occur when more than about 6 ppm of hydrogen is charged indicate the tensile strength of the cold-worked (from machining) steel surface is exceeded.

As much a reappraisal of all the data as time would permit has not disclosed sufficient evidence to extend our analysis except for one factor. It should be emphasized that the division of high and low curve samples was on a general basis, and no definite curve of increased flow stress vs. hydrogen content was obtained with the accuracy of our experiments. Likewise, the proposition that stress at maximum load is not changed cannot be supported by our data. However, for the slow strain rate specimens, the strain at maximum load was noticeably less than for the usual rate tests. Perhaps some hardness reading change would be noted in hydrogen-charged specimens if the hardness tests were performed at a slow rate of application of load.

**P. Bastien and P. Azou** (*Ecole Centrale des Arts-et-Manufactures; Laboratoire de Physique des Métaux, Paris, France*)—We think that the measurement of the volume of hydrogen extracted under mercury from steel specimens (previously treated with this gas by pickling or electrolytic action) by degassing at room temperature does not lead to systematic errors when the usual precautions required for mercury handling are taken. Some air can be entrained by specimens when put in mercury, but tests made by one of us indicate that the collected gas contains at least 99 pct hydrogen. Hydrogen concentration in pickled or electrolytically treated specimens is more heterogeneous than in specimens as received from the steel mill. In the first case, it is particularly high at or close to the metal surface. Therefore, we think that degassing by heating in vacuo may be inadequate, for a great part of the hydrogen may be expected to be lost due to the reduced pressure prior to the actual measurements. We should appreciate hearing some details of the degassing practice used by the authors.

Hydrogen collected under mercury at room temperature is the easily diffusing gas which causes embrittlement of pickled or electrolytically treated specimens. One of us has given evidence that a relation exists between the volume of the easily diffusing hydrogen and the brittleness of the metal.<sup>24</sup>

We are particularly interested in the results obtained by the authors with true stress-true strain tensile tests. We also have plotted true tensile curves for an annealed 0.15 pct C steel both with and without hydrogen. The main results have been presented<sup>15</sup> at

Fig. 9—Effect of strain velocity on reduction of area.

Lower curve shows the effect of hydrogen treatment on the reduction of area of the untreated steel in the upper curve at various rates of straining.

the French Academy of Sciences on April 4 and May 9, 1949. The conclusions reached by the authors are in good agreement with ours. Hydrogen influences only the true rupture stress. The true tensile curves are superimposable whether the steel contains hydrogen or not, but the fracture will occur at a lower true stress when there is hydrogen in the steel; a fact in agreement with a smaller reduction in area. Moreover we have shown that when the testing temperature decreases, the true breaking stress is lowered for a pickled steel. This fracture is semibrittle for ordinary and brittle for hydrogen-bearing steels; the phrases "semibrittle" and "brittle" being used in accordance with Shevandin's work.

In addition we have shown that: 1—Iron and steel brittleness due to hydrogen disappears below  $-110^{\circ}\text{C}$  and reappears reversibly by heating above this temperature.<sup>16</sup> 2—The influence of the gas on the elastic modulus and damping capacity will be smaller if the test used to determine the property being studied causes smaller elastic deformation and apparently is reduced with increasing elastic strain during the test.<sup>17</sup> 3—In tensile tests at room temperature with the duration of the test ranging from 1/150 sec to 2 hr 20 min, hydrogen has no effect on the capacity for deformation at high speeds, its effect becoming a maximum for times between 10 sec and 30 min, then becoming gradually smaller with low rates of straining<sup>18</sup> as shown in Fig. 9.

Our views agree with the authors that hydrogen in the proton condition in the iron lattice<sup>19</sup> has, within the elastic range, no effect on the properties of the metal. Under plastic deformation, the hydrogen, probably diffusing through the motion of dislocations, will collect at the volumetric defects at various locations in the metal where, when it can recombine as molecular hydrogen, it will develop triaxial forces which resist deformation by slip and cause hydrogen embrittlement. Since segregation requires diffusion, it will not occur at the lowest temperatures; below  $-110^{\circ}\text{C}$  for our tests, where thermal agitation is too small, nor with high rates of plastic straining when the time is too short for mass displacement of protonic hydrogen.

This is the reason why hydrogen does not alter significantly the impact resistance of steels, which we have measured over a temperature range from  $-70^{\circ}$  to  $18^{\circ}\text{C}$  using standard type specimens. Similarly it is not surprising that there is no difference in the hardness of test pieces of the same steel with and without hydrogen. In hardness testing, the rate of straining is very high and the plastic deformation is

completed before the time required for hydrogen segregation and resultant action.

**J. B. Seabrook, N. J. Grant, and D. Carney**—We are particularly pleased to find our results in such good agreement with the results of Messrs. Bastien and Azou. Our experience with degassing under mercury has not been too satisfactory. Frequently we found large disagreement between values so obtained and those obtained by vacuum fusion in an iron-tin bath. Regarding the degassing techniques used in this work, Messrs. Bastien and Azou are referred to the two papers by Carney, Chipman and Grant, refs. 11 and 12 of the paper. In this connection we believe that the method described in the above papers is by far the most accurate, reliable, rapid, and simple method presently available for hydrogen analysis.

It is difficult to conceive that the so-called "easily diffusing hydrogen" is anything other than the hy-

drogen which occupies the outer position of the specimen.

The absence of a hardness effect in view of the rapid rate of straining during the test would certainly be a feasible explanation as suggested by Messrs. Bastien and Azou.

## Aging Characteristics of Magnesium-Lithium Base Alloys

by P. D. Frost, J. G. Kura, and L. W. Eastwood

DISCUSSION, R. M. Parke presiding

**D. L. Leman** (Dow Chemical Co., Midland, Mich.)—The presentation of this paper is indicative of the continued interest in the high strength properties of some of the ultra-light Mg-Li base alloys. The general observations on the problems of property instability and lack of ductility in the high strength alloys is in close agreement with the results of work done at The Dow Chemical Co.<sup>4</sup>

The authors mention that the alloy 9.5 Mg/Li-7 pct Al-3 pct Sn may have resistance to stress-corrosion cracking nearly equal to that of AZ31A-H24.\* Using a different testing method, we find it to be appreciably less resistant. The stress-time curves for bars spring-loaded in simple tension and exposed up to four years in a rural atmosphere are given in Fig. 13. Although the time before failure occurring at a given stress-level varies considerably for AZ31A-H24, the failures for 9.5 Mg/Li-7 pct Al-3 pct Sn all took place within such a short time that no significant variation would be expected on more extensive testing. The difference between the two alloys would not be readily apparent at stresses as high as those reported in the paper, because failures occur in both alloys in a comparatively short time. For details of the testing method used and other factors affecting stress-corrosion testing see Loose and Barbican.<sup>5</sup>

We have also tested the creep characteristics of 9.5 Mg/Li-7 pct Al-3 pct Sn at 95°F. The sustained-stress which will produce 0.1 pct extension in 100 hr is 15,000 psi as compared to 18,000 psi for AZ31A-H24.

Fig. 13—Stress corrosion of AZ31A-H24 and 9.5 Mg/Li-7 pct Al-3 pct Sn.

It may be well to mention our conclusions at The Dow Chemical Co. based on the extensive investigation of Mg-Li base alloys. Without going into detail on specific compositions it can be said that there are three distinct classes of alloys as follows:

1—Soft ductile alloys which have a cubic or predominately cubic crystal structure. These are outstanding with respect to formability and toughness at a tensile and compressive yield strength level of 20,000 to 25,000 psi.

2—High strength alloys which have a cubic or predominately cubic crystal structure. These compositions may also be of the Class 1 type in the soft condition but their strength can be trippled by precipitation of the MgLi<sub>2</sub>X phase.

3—Intermediate strength alloys which have an hexagonal or predominately hexagonal crystal structure. Maximum strength in these is developed by cold working or the combination of heat treating, cold working, and aging. The typical tensile and compressive yield strength level is 40,000 to 45,000 psi.

Many of the compositions studied possess interesting properties in one respect or another, but none as yet have been found to have a suitable combination of mechanical properties, secondary properties, and service characteristics which would warrant acceptance as a commercial product. In particular the soft ductile alloys have poor creep resistance, the high strength alloys soften on continued exposure at slightly elevated temperatures and in general are quite brittle in the strong condition, and the intermediate strength alloys are characterized by low notch toughness and high stress-corrosion sensitivity.

The approach to the development of a usable alloy of maximum strength must be through a fundamental study of the mechanism of MgLi<sub>2</sub>X hardening. Creep, toughness, stress corrosion, and possibly other secondary properties should be studied on the basis of alloy design.

**P. D. Frost, J. G. Kura, and L. W. Eastwood** (authors' reply)—Mr. Leman's contribution to this paper is greatly appreciated. It is assumed that the stress corrosion and creep tests to which he refers were con-

\* AZ31A-H24 is the newly accepted ASTM designation for AZ31X-h.

ducted on sheet specimens of the 9.5 Mg/Li-7 pct Al-3 pct Sn alloy prepared at Battelle and sent to Dow for this purpose.

It is difficult to correlate stress-corrosion data obtained by two different methods of testing, particularly where so few specimens are involved. The objections to the bending method of loading are recognized. However, these do not offset the usefulness of this type of test, particularly for materials, such as the 9.5 Mg/Li-7 pct Al-3 pct Sn alloy, whose compressive and tensile yield strengths are equal.

Although the Dow and Battelle results are in fair agreement for the highly stressed specimens, the discrepancy between the results for the lower stressed specimens must await further tests for clarification.

We do not have creep data for the 9.5 Mg/Li-7 pct Al-3 pct Sn alloy. However, we are evaluating the creep and stress-rupture characteristics of 9.5 Mg/Li-7 pct Al-1 pct Sn alloy sheet. Under a stress of 30,000 psi, one specimen failed after 58½ hr. Under a stress of 20,000 psi, one specimen has elongated a total of 0.4 pct in 100 hr, including the initial deformation. It is assumed that the Dow values represent total elongation in 100 hr, and not creep rate.

The following additional remarks concerning the corrosion resistance of Mg-Li base alloys may be of interest. Panels of several alloys have been exposed to the semitropical marine atmosphere at Daytona Beach, Fla., since June 7, 1950. The corrosion rates obtained to date for these alloys are given in Table VIII.

One of the authors carries a pocket piece of an alloy containing 87 pct Mg-9 pct Li-4 pct Zn. This specimen

lay on the author's desk in New York City for four years, and for one year has been in contact with pocket keys and other metallic objects. Most of the surface has acquired a thin, dark, protective layer, while the edges remain bright.

The classification suggested by Mr. Leman for the three types of Mg-Li alloys is a convenient one. Although none of the alloys are yet ready for commercial applications, some may be suitable for special applications where low weight is an important factor. For structural purposes, we believe that the "intermediate strength" alloys of Class 3 offer the greatest promise.

## Hydrogen Solubility in Aluminum and Some Aluminum Alloys

by W. R. Opie and N. J. Grant

DISCUSSION, M. Bever presiding

**W. Baukloh** (Bengal Engineering College, Howrah, West Bengal, India)—On p. 1239 of their paper, the authors mention that their results are contrary to evidence presented previously by Baukloh and Oesterlen who observed a minimum in the curves for the solubility of hydrogen in Al-Cu, Al-Si alloys. Attention

may be drawn to the publication by Baukloh and Redjali<sup>9</sup> on hydrogen solubility in aluminum with some alloying elements (Co, Cu, Cr, Fe, Th, Ti, and Sn). The effect of copper published by Baukloh and Redjali were found to be similar to the results obtained by the authors.

**W. R. Opie and N. J. Grant** (authors' reply)—We wish to thank Professor Baukloh for the above information which was not available at the time of publication.

<sup>9</sup> W. Baukloh and M. Redjali: *Metallwirtschaft* (1942) 21, pp. 633-688.

## Dendritic Crystallization of Alloys

by B. H. Alexander and F. N. Rhines

DISCUSSION, M. Bever presiding

**R. W. Ruddle and A. Cibula** (British Non-Ferrous Metals Research Association, London, England)—We have been pleased to see this study of a sadly neglected subject and would like to compliment the authors on an interesting piece of work. In interpreting the results of their investigation the authors suggest that the dendrite arm spacing is governed primarily by heat transfer factors, specifically the ratio "heat of fusion/thermal diffusivity." We think however that, although they have discussed them very fully, the authors have not attached sufficient importance to the effects of concentration gradients in stifling the growth of budding dendrite arms and thus controlling the spacing of those which are able to grow. They state that no direct correlation exists between the arm spacing and freezing range and other constitutional factors, but surely no direct correlation is to be expected since the concentration gradients set up round a growing crystallite and their growth restricting effect should be controlled not only by the freezing range, but also by the slopes of the liquidus and solidus curves and by the rates of diffusion of the solute element in the melt. Unfortunately it is not possible to evaluate the effects of these factors from the information available.

The authors say that: "Because the diffusion of heat and the diffusion of matter obey similar rate laws, it

follows that these factors should support each other in their influence on the crystallization of alloys." If the authors mean by this merely that both these effects can restrict the growth of crystals, we are in agreement; but we would point out that both these effects cannot control the rate of growth at the same time. If the growth of an isolated dendrite in an undercooled melt is controlled by heat diffusion, then at first heat must be liberated during solidification faster than it can diffuse into the surrounding liquid; this will result in the setting up of a heat barrier round the growing crystallite, which will then limit the rate of crystal growth. Conversely, if the growth of the dendrite is controlled by the diffusion of metal atoms, a concentration barrier will be produced which will again limit crystal growth; in this case the liberation of heat of fusion must lag behind the extraction of heat by the surrounding melt. Clearly, both factors cannot control the growth of the individual dendrite at the same time.

Our own tentative picture of the mechanism of solidification in pure metals and alloys is as follows. The rate of growth of an isolated crystallite in an undercooled pure metal melt must be limited by the rate of heat diffusion into the liquid, for, as the authors state, concentration gradients are impossible in pure metals. However, the crystals growing in a molten pure metal rarely are isolated in the melt but are normally

attached to the mould wall from which they grow in a columnar manner towards the center of the casting. It follows that the heat liberated during solidification escapes through the solid wall of columnar crystals instead of into the liquid metal (which, except at the onset of solidification, is at or above the freezing point). The rate at which heat flows through the solid wall and consequently the rate of growth of the wall is governed by the rate at which the mould extracts heat.

This mechanism, we think, also must apply to dilute alloys which solidify in a columnar manner and in which the concentration gradients are too small to be effective. As the proportion of solute increases, however, a critical concentration is reached beyond which the growth-restricting effect of the concentration gradient exceeds the limitation on growth imposed by the rate of heat abstraction by the mould. Beyond this critical concentration, therefore, the mould removes more heat than is being liberated by solidification on the existing crystals; when this happens the melt in front of the initial dendrites undercools and crystallization begins at fresh nuclei in the interior of the melt, as has been observed with aluminum alloys.<sup>15</sup> This change in the mechanism controlling the rate of crystal growth is accompanied by a changeover from a columnar to an equiaxial structure. The concentration at which the change takes place is dependent upon the rate of heat abstraction by the mould, a high rate causing the changeover to take place at lower concentrations.

Because of the absence of a heat or concentration barrier in a metal of high purity solidifying in a columnar fashion as described above, the tendency towards dendritic growth is small and depends upon the fact that deposition of metal atoms from the liquid takes place preferentially on certain facets of the growing crystal. The absence of marked dendritic growth in solidifying pure metals is illustrated by the fact that when metals of high purity (e.g., 99.99 pct pure Al) are slush-cast in sand moulds the solid shell remaining in the mould has a smooth surface, whereas a metal of lower purity (e.g., commercially pure aluminum) leaves a shell whose surface is roughened by the tips of protruding dendrites. The development of concentration gradients in the presence of a solute element greatly enhances the tendency to dendritic growth, and the spacing of the dendrite arms presumably increases with increase in the gradients, much as described by the authors on p. 1271. However, as stated above, we do not agree with the authors when they suggest (p. 1272) that the controlling gradients are heat gradients and not concentration gradients. We doubt whether an apparent rough correlation of the kind shown in Table VIII, between the dendrite arm spacings and the ratio "heat of fusion/temperature diffusivity" establishes conclusively that heat gradients control the dendrite spacing, for it is likely that both heat and concentration gradients follow the same general trends with increasing concentration of solute element. In any case, analysis of the figures for the Cu-Ni and Cu-Sn series of alloys shows that the apparent correlations are not statistically significant, the probabilities that the apparent correlations arose by chance both exceeding 0.05; (we are adhering to normal statistical practice in regarding correlations as nonsignificant when the chance probability is greater than 0.05). It should however be stated that when all the figures for the Cu and Ni-base alloys are considered together, a correlation which is on the borderline of significance is found, the chance probability lying between 0.02 and 0.01.

Finally, we wonder whether the authors in their reply could give some further details of the way in which they measured the dendrite spacings of the different alloys. In particular, the description and micrographs in the paper do not make it clear what they regarded as "fully developed arms" and what as "stunted side arms." We should like to draw the authors' attention to a recent paper by Kostron<sup>16</sup> who measured the "cell size" of a large number of aluminum alloys. So

far as we can see the cell size measured by Kostron is essentially the dendrite spacing measured by the authors. If this is so, the two sets of measurements are completely at variance for in all cases the cell size measured by Kostron decreases with increase in the amount of alloying element.

**A. Hultgren** (*K. Tekniska Hogskolan, Valhallaragen, Stockholm, Sweden*)—This paper is a welcome contribution in a field where altogether too little is known and understood with certainty.

In their attempt at assessing a value for the average dendritic spacing at a given distance from the surface of an ingot, the authors often encountered a mixture of types of dendritic branches with different spacings, as pointed out on p. 1268. It is suggested that this may be due to two or more families of dendritic branches forming in succession at the same place.

In an investigation of solidification structures in 1.10 pct C steel ingots of commercial size<sup>17, 18</sup> it was found that the growing skeleton of each columnar crystal was built up of a number of parallel cruciform stems—plates intersecting at right angles—from which, at a later stage, secondary and tertiary rod-shaped branches developed, also in tetragonal directions. The spacing of the stems as seen in the cross-section of a crystal was considerably coarser than that of the rods. Whereas the former spacing appeared to increase by steps from root to tip of a columnar crystal, the latter increased continuously from surface to axis of the ingot, with no distinction between columnar and free crystals. The continuous lines seen here and there in the authors' Fig. 1 may be sections of plate-like branchings of columnar crystals whereas short, more closely spaced lines may be sections of secondary branches. In such case, sections parallel to the surface may be instructive. It is not, of course, suggested that the features described are necessarily present in all alloys with dendritic structure.

In Tables II, III, and V columnar and equiaxed grain sizes are both given. Does this mean that both types of grains were generally present at position (*m*)?

The authors' detailed picture of the mechanism by which dendritic branching develops appears plausible and, apart from the concept of successively formed idiomorphs, agrees well with an earlier attempt.<sup>19</sup>

Accordingly, and a little differently expressed, it may be said that the dendritic spacing at any point of an alloy crystal is determined mainly by the following two factors: 1—The linear rate of growth of the corner or main stem of the crystal as largely influenced by the degree of undercooling, and 2—the rate of diffusion of the alloying element. In a pure metal heat conductivity would take the place of the second.

As freezing continues inwards and the rate of growth is gradually retarded the shielding effect exerted by the enriched mother liquor gains upon the growing stem and the dendritic spacing is coarsened.

In the many cases where an alloying element was found to coarsen the spacing two factors may act in this direction: 1—Decreased rate of growth owing to lower bulk heat conductivity, and 2—increased diffusion distance and extended shielding effect owing to steeper concentration gradient in the mother liquor; the lower heat conductivity might be expected to have a local effect tending to decrease the spacing but this is probably overshadowed by 1 and 2.

The difference in spacing between primary and secondary branchings at the same place probably results from the cooling rate at any point increasing all the time as the freezing range is passed, the change in composition of the mother liquor meanwhile being of less importance.

The authors' statement that it is only when crystallization proceeds rapidly that dendritic growth is encountered seems to require some qualification.

In steel ingots of large sizes, coarse dendritic free crystals are found in the central region. Their branches have rounded contours, probably resulting from diffusion of alloying elements and surface tension. When

Fig. 11 (left)—Large constituent primary Al-Cu-Fe-Mn phase; smaller dark constituent forms binary eutectic with Al solid solution. The change from the hexagonal mode of growth occurs with depletion of chemical concentration in liquid phase. X500.

Figs. 12 (left center), 13 (right center), and 14 (right)—Influence of the "principal" planes of primary crystallization upon the mode of crystallization of the eutectic phases. Area reduced approximately 80 pct for reproduction.

the dendritic spacing reaches the same order of magnitude as the size of the crystal, so-called globular structure results. There is a smooth transition between dendritic and globular structure. The latter may be produced in ordinary steel ingots by suitable stirring<sup>15</sup> or, probably, by other methods of inoculation. I should be very much surprised if an idiomorphic  $\delta$  or  $\gamma$  Fe crystal were produced by crystallization in molten steel.

**H. Czyzewski** (University of Illinois, Urbana)—The writers have given an excellent report of their study in this field, and this discussion is made only as a small contribution to the writers' extensive work. The statement is made in the paper to the effect that the intrusion of a second solid phase, such as appears in richer alloys of eutectic and peritectic types, seems to be without influence upon the dendrite dimensions. This is presumed to be because the establishment of the dendrite pattern precedes the crystallization of the low melting phases.

It is suggested in this discussion that the writers' conclusion holds true for the early stages of crystallization but that in the final stages there would be an influence on dendrite dimensions due to the large chemical-concentration gradient from the solid dendrite to the core of the remaining liquid phase. Because the writers reported mostly on alloys in which the primary crystals were dominant, the effect in the final stages of primary crystallization of the second phase, that is the liquid, on the primary phase was not observed. The schematic representation (Fig. 10 of the paper) shows that there is an effect on mode of crystal growth, and therefore on dendrite dimensions, which is a function of velocity of the growth. The velocity of growth is a function of, among other things, the chemical concentration in the liquid adjoining the growing crystal. The writers conclude that the rate of heat transfer is probably of greater importance than is the rate of material transfer in establishing the dendrite spacing in metal systems. This conclusion is justified by the data only in the cases in which the liquid phase can continue to produce the primary solid phase.

A study of multiphase alloys requires modifications of these conclusions of the writers. For example, Fig. 11 shows a primary crystal identified as the Al-Cu-Fe-Mn phase which occurs in certain cast aluminum alloys of a commercial grade.\* The primary crystal shows a series of concentric hexagons of quite regular shape with straight sides and sharp corners. The writers made the statement that "corner rounding" must be expected. This rather common idea is not justified on the basis of Fig. 11. Also, the departure from the hexagonal mode of crystallization in this case does not occur as a function of heat transfer but rather as a function of material transfer and the depletion of the liquid phase. It

appears, therefore, that the second phase can exert an influence on the dendrite dimensions.

Conversely, it also may be concluded that the mode of solidification of the primary phase can exert an influence on the mode of solidification of a secondary phase, and therefore on the dimensions of the secondary phase. For example, in Fig. 11 not only the faces of the hexagons are defined but also apparent are the planes passing from the edges of the hexagons through the longitudinal axis of the hexagonal prism. The formation of these "principal" planes of crystallization is subject to interesting speculation. However, these principal planes have an influence on secondary crystallization, in the eutectic in this case, as seen in Figs. 12, 13, and 14.

Perhaps, the following conclusions may be considered. If the rate of material transfer is not greatly affected during the process of primary crystallization, then the rate of heat transfer regulates the dendrite dimensions. However, if the rate of material transfer varies greatly during the process of primary crystallization, then the primary dendrite dimensions and secondary phase dimensions will be affected.

**B. H. Alexander and F. N. Rhines** (authors' reply)—We thank the discussors for their interesting and valuable contributions to this paper. One main point that is brought up repeatedly in the discussion is whether heat flow or material flow is of greater influence on the dendritic growth in alloys. For the reasons given in the paper, we believe that heat flow is the more important, although we recognize that more work must be done before we can be sure.

It should be emphasized that the spacings we measured were what we considered to be the primary arm spacings which are established early in the course of freezing. The formation of secondary and tertiary dendrite arms and their change in shape due to spheroidization was not studied. It is the smaller size of these later generations of arms that determine the "cell-size" measured by Kostron. It is interesting that cell size varies with concentration in a different manner than the arm spacing; we can think of no good explanation for this, although the concentration and temperature would not be expected to be the same during the formation of the later arms as it was when the primary arms formed. We would estimate that the arm spacing in a given alloy is from 2 to 20 times the "cell size."

The grain sizes listed in Tables II, III, and V are the average width of columnar grains or the diameter of equiaxed grains; both types of grain were not found at the same position in an ingot.

\* The constituent was identified using the procedure in Mondolfo's *Metallography of Aluminum Alloys*. Only one etchant, 20 pct  $H_2SO_4$ , revealed the internal structure of this phase as shown in the accompanying micrographs. The etching action produced a relief effect which was deliberately accentuated in photographing and printing.

# The Crystal Structure of V<sub>3</sub>Co

by Pol Duwez

IN the course of an investigation of the V-Co system, two intermediate phases were found. One of these phases corresponds approximately to the stoichiometric composition VCo and is isomorphous with the sigma phase in the Fe-Cr system.<sup>1</sup> The second phase has the composition V<sub>3</sub>Co; its crystal structure is described in the present note.

The alloys were prepared by mixing the two metals in the powder form, pressing a small disk weighing about 5 g at 80,000 psi, and arc melting this disk on a water-cooled copper plate in an atmosphere of pure helium. The details of this technique have been described.<sup>2</sup> The vanadium powder was obtained from Westinghouse Electric Corp., Bloomfield, N. J. This powder is probably of very high purity, since when it is properly sintered or melted in the above-mentioned arc furnace, ductile specimens are obtained. The cobalt powder, from Charles Hardy, Inc., New York, contained 0.5 pct Ni, 0.1 pct Cr, and traces of Si and Fe.

After melting, the V<sub>3</sub>Co samples were sealed in evacuated quartz tubes and homogenized for ten days at 800°C. Powder diffraction patterns were obtained with a 14.32 cm diam camera, using K $\alpha$  copper radiation. The patterns were readily indexed on the basis of a primitive cubic lattice with a parameter equal to 4.675Å. The density, determined by the immersion method, was 6.71 g per cu cm; hence the number of molecules per unit cell is approximately 1.95; i.e., 2.

At this point, the possibility that the structure might be that of beta tungsten<sup>3</sup> became apparent. The beta tungsten structure is described as follows:

Space group O<sub>h</sub> — *Pm*3*n*

2 Co in (a) : 000;  $\frac{1}{2}$   $\frac{1}{2}$   $\frac{1}{2}$

6 V in (c) :  $\frac{1}{4}$ 0 $\frac{1}{2}$ ;  $\frac{1}{2}$   $\frac{1}{4}$ 0; 0 $\frac{1}{2}$   $\frac{1}{4}$ ;  $\frac{3}{4}$ 0 $\frac{1}{2}$ ;  
 $\frac{1}{2}$   $\frac{3}{4}$ 0; 0 $\frac{1}{2}$   $\frac{3}{4}$

(*hhl*) reflection present only if *l* = 2*n*.

Assuming this structure to be the correct one, intensities were computed by means of the usual equation:

$$I \propto p |F|^2 \frac{1 + \cos^2 2\theta}{\sin^2 \theta \cos \theta}$$

where *F* is the structure factor,  $\theta$  the Bragg angle, and *p* the multiplicity factor. The observed and calculated values of  $\sin \theta$  and the intensities are given in Table I. The agreement between the observed and the calculated  $\sin \theta$  is good and there are no flagrant discrepancies between the calculated intensities and those estimated visually. The (*hhl*) reflections for which *l* is odd are not observed, as required by the space group. In addition, the (410), (430), and (531) reflections are missing as expected, because of the special (a) and (c) positions in O<sub>h</sub>. However, six reflections—(110), (220), (310),

(411), (422), and (510)—which have very weak computed intensities were not observed. For these reflections, the structure factor is proportional to the difference between the scattering factors of the two atoms in the structure. Since the scattering factors of vanadium and cobalt are not very different, these reflections are weak. However, by using K $\alpha$  chromium radiation, whose wavelength is just above the absorption edge of vanadium, the effective scattering factor of vanadium may be decreased by one or two units; consequently the difference between the cobalt and vanadium scattering factors is increased. It was, indeed, found that in a powder pattern taken with chromium K $\alpha$  radiation, the three reflections (110), (220), and (310) were actually present. The three other reflections (411), (422), and (510), with spacings smaller than half the wavelength of chromium K $\alpha$ , were obviously not obtainable with chromium radiation.

All the experimental results appear to confirm the beta tungsten structure for V<sub>3</sub>Co. In this structure,

## Twenty-Five More Years of Metallography

by J. R. Vilella

IN accordance with the custom of this society, we are gathered here, as we have every year since 1924, to honor the memory of the eminent American metallurgist and teacher, Professor Henry Marion Howe. Unlike many of the distinguished metallurgists who have preceded me as a Howe lecturer, I cannot bring to you reminiscences of his personality, for it was not my privilege to be associated with Professor Howe, or to be directly one of his students. Yet, Professor Howe and Professor Albert Sauveur, through the medium of their books, were my first teachers of metallography, as they have been of almost all American metallurgists of my generation. As a teacher, and for many years the acknowledged leader of American metallurgists, he exercised a profound influence in the growth of our science and was held in honor by the men of science of his time. I can speak no words of technical appreciation that will add luster to his fame, for by his prophetic vision, his teachings, and his researches he stands among the immortals in the memory of all metallurgists.

In 1926, the third Howe Memorial Lecture was presented by Professor William Campbell<sup>1</sup> of Columbia University, who entitled it "Twenty-Five Years of Metallography." He took as a starting date for his chronology the turn of the century, which coincided with his arrival from England to work in association with Howe at the Columbia School of Mines. In that informative lecture Professor Campbell enumerated the important advances in metallography achieved during the first quarter of the century, and, it now appears, may have established the custom of reviewing such progress every twenty-five years. The scope of Professor Campbell's lecture was as broad as his metallurgical knowledge, for it embraced a wide portion of the field of metallography, both ferrous and nonferrous.

Twenty-five years later, the Howe Memorial Lecture Committee saw fit to assign to me the honor of writing a lecture that would commemorate the work of Henry Marion Howe and would at the same time constitute the 25th anniversary of the lecture by Professor Campbell. The Committee suggested that this lecture might properly be called "Twenty-Five More Years of Metallography," a suggestion that I

have adopted. I must confess, however, that I have not followed the precedent established by Campbell and have narrowed the scope of this lecture to an appraisal of those achievements which in my opinion have contributed most to the progress of microscopical metallography during the past twenty-five years.

### Progress in Metallography

The metallographic methods most widely used today, with the exception of the electron microscope, were firmly established more than twenty-five years ago. In general, our specimens were prepared for microscopic examination in those days in much the same manner as they are today. It is true that new details of technique have been introduced from time to time, and that superior equipment is available today, but on the whole, these improvements have been in the nature of refinements, often a matter of personal preference, and none can be considered essential to the attainment of the ultimate goal of the art and science of metallography, which is to reveal the structure of metallic specimens with unequivocal clarity so that they may be interpreted correctly.

Mechanical metallographic polishing, which was the only method available in 1926, is still universally practiced and still consists of abrading the metallic specimen with a series of abrasives of increasing fineness until a specular surface is attained. We have now the alternative method of electropolishing, but it is not widely used because, except in a few special cases, its results are inferior to those of competent mechanical polishing.

Likewise, most of the etching reagents preferred today were in common use more than twenty-five years ago and were applied in the same manner as they are today. Valuable improvements have been made in the optical and mechanical performance of metallurgical microscopes, but there was no dearth in those days of excellent instruments equipped with achromatic and apochromatic objectives capable of yielding micrographs comparable in quality with the best that we can make today. In fact, it would be a difficult task for any metallographer today to make optical micrographs at magnifications in excess of 3000 diameters that would surpass those made by Lucas more than twenty-five years ago. One of these is shown in Fig. 1. Yet, it is unquestionable that on the whole, the micrographs appearing in the metallurgical literature today are vastly superior to those

J. R. VILELLA is with the Research Laboratory, U. S. Steel Co., Kearny, N. J.

Fig. 1—Partly resolved nodule of fine pearlite. Made by F. F. Lucas prior to 1926. X3650.

of twenty-five years ago. Since progress in metallography is best reflected in the quality of the published micrographs, it suffices to compare those used as illustrations in the volume of the *Transactions* of this Institute which contains the Howe Memorial Lecture of Professor Campbell<sup>1</sup> with those illustrating any recent volume, to appreciate the magnitude of the progress accomplished during the past twenty-five years. But since this notable progress does not stem from new techniques or superior equipment, what brought it about? I believe it is the inevitable consequence of a better concept of what constitutes a properly prepared metallographic specimen. The aim of the metallographer some years ago was the attainment of a highly specular surface of adequate flatness, free from scratches. At the cost of many errors of interpretation and much confusion in our concept of some of the structures of steel, we have learned that these requisites are not enough; that in addition the nonmetallic inclusions have to be preserved intact so that the cleanliness of the steel may be judged correctly, and most important of all, that the polished surface has to be freed from all traces of flowed or disturbed metal before the true struc-

ture of the metal can be seen. Rapid progress began when the idea spread among metallographers that the structure observed in specimens which had been polished and etched just once, was seldom the true structure of the metal. The fact that a polished metallic surface owed its specular finish to a layer of flowed metal had long been known, but the effect of incomplete removal of this layer on the appearance of the structures of steel and other metals was not appreciated. In fact, it was generally assumed that this layer of flowed, or amorphous metal, as it used to be called, was removed completely during the first etching and therefore very few questioned the authenticity of a structure revealed in a sample polished by a competent operator and etched in one of the standard reagents. It is my belief that our failure to rid the surface of metallographic specimens of this insidious layer of disturbed metal was one of the most subtle but effective obstacles blocking progress in our knowledge of the structures of steel and that it entailed consequences from which metallography has but recently recovered.

We need only to recall our concepts of some of the structures of steel prevalent about 1926, and the nomenclature and phraseology that grew logically out of those concepts, to appreciate how greatly our ideas have changed since it became possible to see the true configuration of the structures of steel. It was then generally agreed that pearlite was the structure resulting from direct transformation of austenite and exhibiting alternate lamellae of ferrite and carbide, Fig. 2. Martensite was universally recognized as the slow-etching acicular structure of great hardness resulting from low temperature transformation of austenite and generally obtained by cooling steel rapidly from the austenitizing temperature, Fig. 3. Likewise, there was no hesitancy in identifying as troostite, the dark etching, nodular structure often found associated with martensite in rapidly cooled steels, Fig. 4. In the high carbon alloys there was no difficulty in identifying ledeburite or proeutectoid cementite occurring either as a massive network or as primary needles. These are illustrated in Figs. 5 and 6 respectively. Mixtures of martensite and retained austenite, such as illustrated in Fig. 7, were likewise readily recognized in very high carbon steels. However, if the structure observed under the microscope was a dark-

Fig. 2 (left)—Pearlite 0.89 pct C steel transformed isothermally at 1325°F. X2500.

etching conglomerate that could not be resolved into lamellae, then the metallurgist had to decide whether it was troostite or sorbite. Since these structures lacked characteristic patterns or configurations on which to base identification, the decision on what to call such a structure depended on the heat treatment that the steel had received. The structure was considered to be troostite if it had been obtained either by tempering martensite at slightly below 750°F or by cooling through the transformation range at a rate slower than that required to form martensite, as for example, by oil quenching, or in the middle of large pieces quenched in water. It was sorbite if produced by tempering martensite between 750° and 1300°F or by air cooling small pieces from the austenitizing temperature. In other words, it was generally accepted that essentially the same structure resulted from the decomposition of austenite on cooling and from the decomposition of martensite on tempering, although by 1926 there was an increasing number of metallurgists who questioned the correctness of that view. We find, for instance, that Professor Campbell in his Howe Memorial Lecture of that year asks, "But have we strong enough evidence to prove that it (troostite) is the same as the secondary troostite that occurs

on cooling?" However, the fact is that the only reason this question had to be asked in 1926 was because, in spite of excellent microscopes and fine apochromatic objectives, we were unable to see that the structures resulting from the direct transformation of austenite were lamellar, whereas those derived from the tempering of martensite were granular. And the reason we could not see this fundamental difference, clearly shown in Figs. 8 and 9, was because our microscopes were focused on a false surface, just a few atomic layers in thickness, over the surface that would have given us a definitive answer. It was our inability to see beyond this false surface, more than any other cause, that gave permanence to the old concepts of sorbite and troostite.

After more than a quarter century of active participation in furthering the art and science of metallography, it is my considered opinion that recognition of the existence of a layer of disturbed metal formed during polishing and its elimination by the practice of alternate polishing and etching, Fig. 10, has been one of the observations that has contributed most to our knowledge of the structures of steel and to the progress of metallography in general. Yet, even after we were able to see clearly, our understanding and proper interpretation of these struc-

Fig. 10-a (left)—Disturbed metal produced during polishing. b (right)—Disturbed metal eliminated. X1000.

tures might have been delayed had it not been for a contribution from the field of physical metallurgy that I propose to discuss briefly.

This was the investigation by Bain and Davenport into the decomposition of austenite that led to the development of the isothermal transformation diagram. This method of investigation in a comparatively few years turned the emphasis in metallurgical thinking and research from the study of the constitution of alloys after attaining equilibrium at various temperatures to the study of the reactions in solid steel responsible for the aggregate structures, which in turn determine the properties of the alloy. Since the publication of their first paper<sup>8</sup> on the transformation of austenite at constant subcritical temperature in 1930, there have been few major contributions to our knowledge of steel metallography outside of the field of inquiry opened by this epochal work. Its contributions have been in many directions; it established the relation of transformation temperature to type of structure; it enabled us to measure rate of transformation in solid steel; it taught us how alloying elements and variations in austenite grain size exert their influence on hardenability; it disclosed the interrelation of the structures; it gave us a new family of structures, the

bainites, Figs. 11 and 12, whose valuable properties are finding increasing application in diverse industries; it provided us with a scientific basis for revision of the obsolete nomenclature of the structures of steel; and most important of all, it transformed the heat treatment of steel from an art into a science.

In the struggle to rid the metallographic specimen of disturbed metal, the introduction of electropolishing was a welcome aid. For many years we realized that practically every metallographic specimen of austenitic, low carbon stainless steel exhibited striations and figures that were purely a surface condition produced during its preparation. The elimination of these false structures by the technique of alternately polishing and etching, employed with such success in carbon and low alloy steels as well as in nonferrous alloys, proved inadequate when applied to soft austenitic steels. Quite often we were forced to accept the presence of these defects in micrographs intended for publication because we were unable to eradicate them. With the advent of electrolytic polishing this vexatious condition disappeared. If we cannot by ordinary mechanical polishing, we can now by electropolishing, reveal the structure of the softest austenitic al-

Fig. 11—Bainite 0.89 pct C steel transformed isothermally at 550°F. X2500. a (left)—Partial transformation. b (right)—Complete transformation.

Fig. 12—Bainite 0.89 pct C steel transformed isothermally at 850°F. X2500. a (left)—Partial transformation. b (right)—Complete transformation.

loys free from confusing artifacts, as may be seen in Figs. 13 and 14. Unfortunately when electropolishing is applied to steels other than the stainless grades, it often results in excessive pitting of the nonmetallic inclusions and for this reason we do not often encounter in the literature micrographs made from electropolished surfaces. However, the method is finding increasing application in the preparation of specimens intended for routine examination at low power, and may lead, by simplifying their preparation, to more frequent use of the microscope as a tool of routine inspection.

Not many years ago a micrograph was considered satisfactory if the structure photographed was recognizable. Such defects as uneven illumination, pits resulting from dislodgement of nonmetallic inclusions, excessive or insufficient contrast, or incomplete removal of disturbed metal were all too common. Today any of these defects is deemed intolerable by an increasing number of metallographers. The excellence of the micrographs entered in competition every year at the American Society for Metals and other metallurgical conventions attest to the craftsmanship of many of our younger metallographers and to the pride they feel in achieving a beautiful photographic representation

of a structure. Yet, careful examination of these selected micrographs often reveal deficiencies directly traceable to inability of the metallographers to make proper use of the adjustments and associated apparatus provided by the manufacturer of microscopes for improvement of the image. Such deficiencies, small as they are in contrast with the gross defects of years past, are nevertheless a glaring reflection of shortcomings in the training of metallographers. The microscope is their all-important tool, but because they are not always conversant with the principles of optics underlying the instrument, they often fail to utilize its full potentialities. They are expected to produce a faithful photographic reproduction of a microstructure, but they have not been trained in the art and science of photography sufficiently to use this very flexible process with skill and artistry. There is probably no greater contribution that our colleges can make toward future progress in the art of metallography than to stress the teaching of the fundamental principles of microscopy and of photography.

### The Electron Microscope

Ever since the introduction of the electron microscope metallurgists have believed that the great

Fig. 13—18-8 stainless steel. X100. a (left)—Polished mechanically. b (right)—Polished electrolytically.

resolving and magnifying power of this instrument would be of inestimable value in exploring the fine microstructures of steel and in the study of metallurgical processes involving precipitation of constituents too fine for resolution with the optical microscope. The first attempt in this direction demonstrated the ability of the microscope to resolve significant details beyond the limits of the optical instrument, but it was immediately apparent from the markedly dissimilar results obtained by different investigators that before its inherent advantages could be realized the causes leading to such diversity of results had to be ascertained and eliminated.

It was the consensus of a group of electron microscopists and metallurgists that by concerted study of the various steps involved in the production of an electron micrograph it should be possible to arrive at a degree of standardization of procedure that would result in satisfactory agreement between different investigators as to the appearance of presumably similar structures. To accomplish this purpose the Joint Committee on Electron Microstructures of Steel was organized in 1948 and a program of investigation formulated, consisting of heat treating a series of pieces of eutectoid steel and dividing these pieces into specimens which were supplied, together with a high-power optical micrograph of each structure, to each of the cooperating laboratories for study with the electron microscope. In 1949 this group became affiliated with Committee E4 on Metallography of the American Society for Testing Materials and in 1950 the first progress report of this work was published. It is this report that I wish to review today because in my estimation it represents a contribution to our knowledge of the structures of steel.

Paraphrasing the conclusion and summary of this report, the work of this Committee demonstrates, first of all, that high fidelity electron micrographs of the structures of steel can be obtained by present-day replica techniques. This is evidenced particularly by the close similarity in appearance between light and electron micrographs of such structures as pearlite and spheroidized carbides which, because of their relative coarseness, can be well resolved with the optical microscope, see Fig. 15.

Inasmuch as these micrographs leave little doubt that faithful reproductions can be made by the

replica technique of electron metallography, our confidence is greatly strengthened in the ability of the method to show us the true appearance of those structures that are too fine for adequate resolution with the optical microscope. Likewise, there should be little hesitancy in the use of electron micrographs for measurement of structural dimension, whenever such measurements are desired.

Considering some of the fine structures of steel, we see in Fig. 16 that the structure resulting from the transformation of austenite in the vicinity of the nose of the isothermal transformation diagram, which for years we had inferred was finely laminated pearlite, is actually just that.

It will not be possible to present all the micrographs contained in this report but it would be remiss to omit those that can teach us something. For example, the microstructure of bainite formed at 750°F, shown in Fig. 17, appears to have been completely resolved and found to consist of discrete, chunky cementite platelets, more or less randomly distributed and oriented in the ferrite matrix. The length of these platelets is estimated to vary between 600 and 1000Å, with the larger size predominating.

Fig. 18 indicates that the structure of bainite obtained by isothermal transformation at 500°F consists of ferrite bands containing cementite platelets in parallel array.

No definite fine structure is identifiable in the needles of untempered martensite, as may be seen in Fig. 19, but the sharp definition of even very small areas of retained austenite suggests that the electron microscope would be of value in improving the accuracy of quantitative estimations of retained austenite.

While attention is focused on Fig. 19 exhibiting comparatively soft austenite in hard martensite, permit me a brief digression to point out that all these micrographs were obtained from surfaces polished as for optical metallography, yet, in spite of the high resolution and magnification of the electron microscope, no scratches or other imperfections attributable to mechanical polishing are detectable. This is significant because it attests to the adequacy of the technique of polishing on which optical metallography has always depended. Likewise, since our concept of the appearance of the structures of steel has been based on the use of

Fig. 14—18-8 stainless steel. a (upper left), b (upper right), and c (lower left) are false structures produced during mechanical polishing. d (lower right) is the true structure obtained by electrolytic polishing. X500.

pical and nital as etching reagents, it is indeed fortunate that these solutions have been found equally satisfactory for electron metallography.

The structure of martensite tempered at 400°F, illustrated in Fig. 20, is of particular interest for two reasons; first, because it shows that the precipitate responsible for the dark-etching characteristic of this structure is of such extreme fineness as to tax even the resolving power of the electron microscope, and second, because the areas of untransformed retained austenite so clearly shown in the optical micrographs are not identifiable in the electron picture.

Since, according to the isothermal transformation diagram for this steel, a considerable amount of the original retained austenite should remain untransformed after tempering 1 hr at 400°F, our inability to identify it in the electron micrograph can only be interpreted as a failure of the method to reveal clearly the true structure of the specimen. X-ray analysis shows that this specimen contains 9 pct of retained austenite.

Likewise, the optical micrograph and X-ray analysis of the specimen tempered 1 hr at 800°F, Fig. 21, indicates the disappearance of the last traces of retained austenite, which must have transformed isothermally to 800°F bainite during tempering, yet in the electron micrograph, martensite tempered at

800°F cannot be differentiated from bainite formed at the same temperature.

In calling attention to the apparent failures of the electron microscope to reveal subtle differences in the structure of steel my only purpose has been to emphasize my opinion that further refinements of technique are necessary before the full potentialities of this instrument are realized.

### Microscopes

The first step in the development of the modern metallurgical microscope dates back to 1872 in Vienna, when V. von Lang<sup>3</sup> first fitted a microscope with a plain glass vertical illuminator in order to examine opaque objects. This was followed in 1897 by Le Chatelier's<sup>4</sup> design of an inverted instrument that made it possible, by merely placing the specimen on the stage, polished surface down, to attain the necessary perpendicularity to the optical axis. By 1926 this design had been adopted by the leading manufacturers of microscopes, and inverted instruments equipped with plain glass vertical illuminators had become standard equipment of the metallurgical laboratory. Numerous mechanical improvements and refinements, some of them marvelously ingenious, have been made in recent years and the versatility of the instrument has been increased many fold by the addition of several more or less

Fig. 15—Pearlite 0.87 pct C steel transformed isothermally at 1300°F. a (left)—Light micrograph X2500. b (right)—Electron micrograph X15,000.

Fig. 16—Fine pearlite 0.87 pct C steel transformed isothermally at 1100°F. a (left)—Light micrograph X2500. b (right)—Electron micrograph X15,000.

useful attachments and accessories. It is the merits of these supplementary accessories that I propose to discuss now.

The first of these, and in my estimation the most valuable, was so-called conical illumination invented by Harry S. George,<sup>5</sup> then with the Union Carbide and Carbon Research Laboratories. The invention was made about 1922 but it was not incorporated into metallurgical microscopes until after 1926. With this simple but effective device it became possible to cut off from the illuminating pencil of light the central, more or less parallel rays, and by utilizing only inclined rays, to illuminate the specimen obliquely, thereby creating highlights and shadows that reveal with stereoscopic realism the three dimensions always present in polished and etched metallic surfaces.

While the geometric exactitude of a micrograph made with axial illumination may be unimpeachable, it is not a truly "natural" representation of the structure and sometimes it is not a satisfactory one. An image or a micrograph lacking such gradations of light and shadow as are encountered in objects illuminated by oblique light is little more than a drawing of a two dimensional pattern, or a map of

the structure in which elevations and depressions are not identifiable. Such representation of the structure is likely to be deficient technically as well as aesthetically, for in many structures significant detail is often not visible except when the highlights and shadows created by oblique lighting bring it out in relief. (See Figs. 22 and 23.)

Unfortunately, the very virtue of conical illumination by which it brings out hidden details and enables us to see the natural contours of a structure, discourages its use, for it also placed in bold relief polishing imperfections which the metallographer would rather not emphasize. But although micrographs made under conical illumination do not appear in the metallurgical literature as frequently as they deserve, conical illumination is nevertheless the most nearly indispensable of the supplementary accessories, for the need of knowing whether a constituent is in relief or in intaglio arises during a metallographic examination more often than the need to examine the structure under polarized light, dark field illumination, or phase contrast.

In addition to conical illumination, the modern, up-to-date, metallurgical microscope is equipped for viewing the specimen under polarized light,

Fig. 17—Bainite 0.87 pct C steel transformed isothermally at 750°F. a (left)—Light micrograph X2500. b (right)—Electron micrograph X15,000.

Fig. 18—Bainite 0.87 pct C steel transformed isothermally at 500°F. a (left)—Light micrograph X2500. b (right)—Electron micrograph X15,000.

dark field and phase contrast illumination. Each of these systems of illumination contributes from time to time valuable items of information and their place in the metallurgical microscope is justified, but to date their contributions to our knowledge of the structure of steel have been decidedly minor.

Examination of unetched surfaces with reflected polarized light under crossed Nicols sometimes enables the metallographer to distinguish between inclusions having isotropic and anisotropic properties, and these characteristics together with the color reflected through transparent inclusions from the metal-inclusion interface, sometimes helps in identifying the inclusion. The vitreous character of some globular nonmetallic inclusions has been shown by the appearance of a dark optical cross when examined under crossed Nicols. Several investigators have made use of reflected polarized light in the identification of constituents, such as sigma phase in iron-chromium alloys; others to delineate grains in martensite, but these applications have been few and as yet the value of the method in the identification of constituents has not been proven.

The contribution of dark field illumination has been primarily to enhance contrast when such en-

hancement was deemed desirable. This enables one to see clearly grain boundaries and other details of structures not readily visible under bright field illumination because of insufficient contrast. Professor Desch<sup>6</sup> finds it particularly useful in the examination of deeply etched or pitted specimens, as when studying surface corrosion. He reports that, "pits which appear under vertical illumination merely as black spots may be examined in detail, the color or form of the corrosion product contained in them being clearly seen." At low power, when the depth of field is considerable, it is very useful in examining unpolished surfaces, for it reveals the colors of the specimen with greater brilliancy and fidelity than with any other form of illumination.

#### Phase Contrast

Another optical accessory recently made available for incorporation into the metallurgical microscope is an attachment for illuminating the specimen under the conditions known as phase-contrast. The theory and graphic representation of this system of illumination is too involved for presentation in a paper of this type, but the following may give an idea of its potential usefulness to metallography.

Fig. 19—Martensite and retained austenite 0.87 pct C steel water quenched. a (left)—Light micrograph X2500. b (right)—Electron micrograph X15,000.

The distribution of brightness throughout an image as we see it with an ordinary microscope depends on: 1—relative reflectivity of various parts of the structure, or 2—color differences, or 3—light scattered away from the objective by edges in the structure. It may be noted that it does not depend on differences in level at the surface of the specimen. In other words, two parts of the structure at different levels, their color and reflectivity being equal, will appear equally bright. However, by means of the phase-contrast system of illumination differences in level, which produce differences in the phase of the light reflected from them, are converted into differences in brightness, and hence the term phase-contrast.

It is claimed<sup>7</sup> that by this means it is possible to show differences in level of the order of 50Å (approximately 20 interatomic distances) and there is no question that for this purpose the method has great sensitivity, but as yet we do not know what use to make of the information supplied by this sensitive, ingenious method. It is also claimed that phase-contrast is sensitive to differences in surface material,<sup>8</sup> a claim that your speaker was unable to substantiate during his limited experience with this system of illumination. However, if this claim is

found to be valid and incident phase-contrast can be employed to differentiate constituents which under ordinary illumination appear identical, then regardless of the usefulness of data pertaining to differences in level, the method will become a valued tool of metallography.

The contribution of phase-contrast illumination to our knowledge of the structure of steel to date has not been significant, but the tool has been available to metallographers for a short time and it would be premature to pass judgment on its eventual merit.

#### Coated Lenses

A development in the manufacture of photographic lenses which in recent years has aroused considerable interest and which, when extended to microscope objectives and eyepieces, led to a marked improvement of the image, is the anti-reflection coating applied to glass-air interfaces in order to decrease internal reflections, or flare.

In a metallurgical microscope the objective acts first as condenser to illuminate a portion of the polished surface and then as a lens to form an image of the illuminated field: Thus the opportunity for reflections are double those of a microscope used with transmitted light, and consequently, excessive

Fig. 20—Tempered martensite 0.87 pct C steel quenched in water and tempered 1 hr at 400°F. a (left)—Light micrograph X2500. b (right)—Electron micrograph X15,000.

Fig. 21—Tempered martensite 0.87 pct C steel quenched in water and tempered 1 hr at 800°F. a (left)—Light micrograph X2500. b (right)—Electron micrograph X15,000.

internal reflections have been one of the most common and serious defects of objectives designed for metallography. When the illumination is by transmitted light the unwanted reflection is in the direction of the light source and can only reach the image after a second reflection, when its intensity is so low that its effect on the contrast of the image is negligible. On the other hand, when the illumination is by reflected light, the undesirable internal reflection is in the direction of the image and of sufficient intensity to produce a decided veiling effect that impairs seriously the contrast of the image, particularly when the reflectivity of the specimen is low.

To a very considerable extent this defect has been corrected by coating the objective and eyepiece with a transparent film whose thickness is approximately one fourth of the wavelength of the incident light. When the film material is of the correct index of refraction, the light reflected from the glass-film and from the film-air interfaces interfere destructively and only an inconsequential amount of light is then reflected from the surface.

There is another aspect to the application of anti-reflection coating to objectives and eyepieces of great interest to those of us who enjoy making the

best possible micrographs. Since in order to disclose the finest and most delicate details it is necessary to etch lightly, the resulting contrast between the various constituents of the structure is so slight that we are forced to compensate by using photographic plates or films of very high contrast. But since high contrast emulsions are necessarily of slow speed, we have to resort to a strong source of illumination, such as the carbon arc. This is undesirable, for the carbon arc at its best is an unreliable source of the steady, even illumination needed for micrography. The tungsten ribbon filament is definitely preferable, for it gives a steadier and more uniform illumination and is also more convenient to operate, but it cannot always be used, particularly at high magnification, because of insufficient intensity for micrography on slow, high contrast emulsions. But the improvement in contrast brought about by coated optics is sufficiently great to permit the use of faster, lower contrast emulsions and this in turn allows the use of incandescent bulbs. Since the tone range of slow, high contrast emulsions is short, an improvement in tone gradations generally accompanies the use of faster, lower contrast emulsions.

#### Interference Filters

Since not even the finest apochromatic objectives are fully corrected for all colors of the spectrum, it is necessary, if we are to avoid images blurred by residual aberrations, to suppress those wavelengths for which the objective is not corrected completely. For this purpose we employ light filters, mostly in the form of colored glass or gelatin sheets dyed and cemented between glass plates of adequate flatness. The yellow-green filter ordinarily used with achromatic objectives, or the blue-violet often employed to increase the resolving power of apochromats are, in a general way, satisfactory for all but the most exacting metallographic work, but they fall short of performing their intended function ideally since the portion of the spectrum which they transmit is sufficiently wide to include wavelengths for which the objective is not corrected adequately. The ideal filter would be monochromatic, that is, one transmitting only a narrow range of wavelengths in the immediate vicinity of the dominant color. Close approximations to such ideal filters are now available in the form of interference filters.

An interference filter of the transmission type

Fig. 22—Conical illumination. Austenite 1.2 pct C, 6.0 pct Mn steel quenched in brine from 2000°F. X500.

Fig. 23—Conical vs. axial illumination. Ferrite and martensite. a (left)—Axial. b (right)—Conical. X1000.

consists of two semitransparent films of silver separated by one of magnesium fluoride, these three films being deposited on a glass plate with a cemented cover glass for protection. The glass plate and cover glass are not shown in Fig. 24 which is a rather oversimplified schematic representation of the path of a light ray through the filter. The

Fig. 24—Path of light through a transmission-type interference filter.

diagram as well as the following description are taken from a Bausch and Lomb publication:<sup>9</sup>

"When the light ray strikes the first silver film part of it is transmitted and passes through the magnesium fluoride coating to the second silver film. Here it is partly reflected and partly transmitted. This process is repeated and this gives rise to multiple reflections between the silver films, and produces a great number of emergent beams. Since the layer of magnesium fluoride is half a wavelength thick and since each doubling back of the light ray forces it to travel twice

this distance, the successive emergent rays are precisely one wavelength apart. When this condition is fulfilled, maximum transmission of light of a particular wavelength occurs and light of other wavelengths is blocked. Consequently the color of the light produced will be determined by the thickness of the coating of magnesium fluoride. In short, the wavelength and, therefore, the color of the emergent light may be precisely controlled; the production of any desired color thus becomes a matter merely of the choice of film thicknesses."

An example of the quality obtained with an interference filter is shown in Fig. 25.

### Color Metallography

Micrography in color is not a development of recent years but dates back probably to 1907 when the Lumiere Autochrome process was introduced commercially. Your speaker made micrographs in color of certain structures in aluminum alloys more than twenty-five years ago. Neither the exposure using a carbon arc nor the development of the plates presented any particular difficulty, and the resulting transparencies were pleasing to look at and accurate as to color rendition. Their main limitation was that when viewed magnified by projection, as in a lantern slide, the colored starch platelets which constituted the color filters of the process, could be seen simultaneously with the image. This granularity reduced somewhat the definition of the finest details of the structure.

With the introduction in more recent years of color films having a high order of resolving power and comparative ease of development in the laboratory, such as Eastman Kodak Ektachrome, or Ansco Color Film, there has been a rebirth of interest in color metallography and some interesting micrographs appear in the literature from time to time. There is no doubt that brilliantly colored subjects are reproduced more faithfully in color transparencies or prints than in black and white and in certain cases the added cost and difficulties inherent in color micrography are fully justified, but one must guard against the temptation of photographing in color for no reason other than making colorful pictures.

In the photographic reproduction of biological subjects where differential staining for purposes of identification is essential, and in metallography when color differences are significant, micrography in color

Fig. 25—Tempered martensite 0.87 pct C steel made with an interference filter transmitting  $\lambda 4200\text{\AA}$ .

Fig. 26—Ultraviolet microscopy. Pearlite, 1300°F, 0.87 pct C steel. a (left)— $\lambda 5460\text{\AA}$ . b (right)— $\lambda 3650\text{\AA}$ . X2000.

is of unquestionable value. However, in many applications of ferrous metallography, where color differences other than variations in shades of gray are rare, its extended use can hardly be justified. If someday, paralleling the technique of the biologist, we learn to identify constituents or structures in steel by differential staining, then color metallography may become an indispensable tool of steel metallography.

#### Photographic Materials

The metallographer has always been fortunate in having at his command a wealth of photographic emulsions from which to choose one well suited to the contrast of his subject. Yet, from the beginning the tendency has been to use exclusively glass plates coated with emulsions of high contrast. For a high percentage of micrographs emulsions of high contrast are the correct choice, although their exclusive use often results in unpleasant black and white reproductions devoid of half tones. But regardless of the type employed there is no valid reason why an emulsion intended for metallography should be coated on glass rather than on film. We are told that the superior flatness of plate glass is desirable for micrography at high power, but actually, except in rare instances when it is desirable to make pre-

cise measurements on the photographic negative, the flatness of films inserted in well-made sheaths is perfectly satisfactory at all magnifications.

There are two distinct disadvantages to glass plates; they are liable to breakage and, because of their bulk and weight they require specially strong cabinets for filing and storage and much floor space. One would gladly overlook these disadvantages if in some small measure they were compensated by some advantage in favor of glass plates, but in truth, glass as a supporting medium for emulsions specially compounded for metallography has no merit to justify its continued use. The manufacturers of photographic materials would render a distinct service to metallography if they would coat on film an orthochromatic emulsion of medium speed which could be developed to a wide range of contrast. Such film would not need to be extremely fine grained, since in optical metallography contact printing is the usual practice.

#### Ultraviolet Microscopy

The metallographer has long been interested in ultraviolet microscopy for two reasons; as a means of increasing resolving power and as a possible means of structural differentiation by differential

Fig. 27—Ultraviolet microscopy. Fine pearlite and bainite, 950°F, 0.87 pct C steel. a (left)— $\lambda 5460\text{\AA}$ . b (right)— $\lambda 3650\text{\AA}$ . X2000.

Fig. 28—Ultraviolet microscopy. Bainite, 750°F, 0.87 pct C steel. a (left)— $\lambda 5460\text{\AA}$ . b (right)— $\lambda 3650\text{\AA}$ . X2000.

absorption. The first of these reasons is a reality, the second, a possibility not yet sufficiently explored.

According to Abbe's well-known formula, the resolving power of an objective is proportional to twice the numerical aperture (N.A.) and inversely proportional to the wavelength of the light used. This means that resolution can be improved either by increasing the numerical aperture of the objective or by decreasing the wavelength of the light used. The question of greatest interest to the metallographer is, which of these alternatives is preferable? In answering this question let us consider the extreme differences in numerical aperture existing between electron and light microscopes. The numerical aperture of the magnetic lens of an electron microscope is of the order of 0.001, that is, about 1600 times smaller than that of a 1.6 N.A. monobromonaphthalene immersion objective, which has the greatest aperture of all the objectives available for metallography. On the other hand, the wavelength of the green light generally used in metallography is about  $5500\text{\AA}$  as compared with  $0.05\text{\AA}$  for the electron radiation, that is, the electron microscope employs wavelengths more than 100,000 times finer than those used in the light instrument.

In consequence of these great differences, micrographs made with the extremely small aperture of a magnetic lens are critically sharp and possess remarkable depth and flatness of field even at the highest magnification of the electron instrument, while those made with a light microscope, because of the relatively wider aperture of glass objectives, are of shallow depth of field and except at low magnification, seldom in optimum focus outside of a small area in the center of the field. Sharp focusing with an electron microscope at any magnification within its range is no problem at all, but making a micrograph in good focus with a 1.6 N.A. objective using blue light at a magnification of 2500 diameters is an achievement, and in all candor, more a matter of good luck than of skill.

The preceding comparison indicates the advantages of increasing resolution by employing illuminants of short wavelength rather than by resorting to objectives of higher numerical aperture. This question was raised because the need for choosing between objectives of high numerical aperture using visible light and objectives of lower aperture using ultraviolet is a distinct possibility in the not too distant future. Even today the metallographer who

Fig. 29—Ultraviolet microscopy. Tempered martensite, 1 hr at 800°F, 0.87 pct C steel. a (left)— $\lambda 5460\text{\AA}$ . b (right)— $\lambda 3650\text{\AA}$ . X2000.

wishes to resolve the finest detail possible with an ordinary metallurgical microscope has a choice of two objectives of approximately equal resolving power, one of numerical aperture 1.6 corrected for blue light of wavelength in the vicinity of 4500Å and one of numerical aperture 1.3 corrected for ultraviolet light of 3650Å. The theoretical limit of resolving power of both objectives is about 0.14 microns.

The ultraviolet objective referred to is not a recent development;<sup>30</sup> it was manufactured commercially by Bausch and Lomb Optical Co. about 1930, but for some unknown reason it was never used extensively in metallography. It was designed so that the green mercury line with wavelength 5460Å and the ultraviolet of 3650Å are simultaneously in focus. This makes it possible to focus with a green filter, substitute a filter with maximum transmission at 3650Å and make the exposure. Since the absorption of ultraviolet light of 3650Å wavelength by glass is slight, no change from glass to quartz of any part of the optical system is necessary. However, oil of sandalwood is preferable to cedar oil for the immersion medium because it absorbs less of this wavelength.

The process is simple and the results are gratifying, as may be judged from Figs. 26 to 29 inclusive. I am unable to present to you a direct comparison of the same structures photographed with a 1.6 N.A. objective using visible light and with the 1.3 N.A. ultraviolet light of 3650Å wavelength, but there is no doubt in my mind that the image of the ultraviolet objective is superior in resolution, flatness, depth of field and in freedom from flare.

A convenient source of ultraviolet light is the high intensity mercury lamp, type H4, obtainable from General Electric Co. or in a housing for micrography from Bausch and Lomb Optical Co. The exposure for micrographs at 2000 diameters using Corning filter No. 5680, 5 mm thick, varies between 5 and 15 min, depending on the speed of the photographic emulsion and the reflectivity of the structure. Since ultraviolet images tend to be low in contrast, high contrast emulsions such as Kodak Process Ortho, or the equivalent product of other manufacturers, are preferable. The resulting negatives possess sufficient contrast to print well on No. 1 contact printing paper.

Another possibility of a practical system of ultraviolet metallography exists in the application in this field of the reflecting objectives recently introduced for ultraviolet microscopy by transmitted light. These lenses have the very attractive property of being achromatic over a wide range of wavelengths, including both visible and ultraviolet portions of the spectrum. They offer the possibility of attaining a resolving power equivalent to that of a refracting objective of numerical aperture 2.0 without the very serious limitations that such an objective would have if it existed. Since they are achromatic for visible and invisible light, focusing for micrography with the shortest wavelengths in the ultraviolet would be no problem. Fig. 30 was made with a water immersion reflecting objective of numerical aperture 1.1, adapted experimentally for use by reflected incident light and loaned to your speaker by Bausch and Lomb Optical Co. This is possibly one of the first micrographs of a metallic specimen made with a reflecting objective.

Since with these objectives it would be possible to photograph a structure with ultraviolet light of

Fig. 30—Ultraviolet microscopy. Bainite. Micrograph made with a reflecting objective using ultraviolet light of  $\lambda 3650\text{\AA}$ . X2000.

different wavelengths, they offer a means of investigating the possibility of identification of structures and constituents by selective absorption.

However, these objectives are not yet available for use in metallography and therefore an appraisal of their contribution to the advancement of our science may have to wait until a future Howe lecturer reviews the achievement of the next twenty-five years.

### Summary

It may be said by way of recapitulation, that the progress achieved in the preceding quarter century in our understanding of the structures of steel was brought about by the following accomplishments:

1—Elimination of disturbed metal from the surface of metallographic specimens. This enabled us to see the true configuration of the structures of steel.

2—Development of the isothermal transformation diagram. This helped us to understand the structures unveiled by the elimination of disturbed metal.

3—Application of the electron microscope to the study of the structures of steel. This enabled us to see finer details than we have seen before and brought us closer to definitive resolution of the structures.

# Arc Melting of Titanium Metal

by S. F. Radtke, R. M. Scriver, and J. A. Snyder

**An automatic, continuous casting arc furnace employing a nonconsumable electrode and a direct current arc has been constructed and operated successfully for titanium. A comparison of the properties of arc and induction-melted titanium indicates that where high ductility, formability, and toughness are required, arc-melted metal is preferable.**

**B**ECAUSE of the reactivity of titanium metal with all known refractories and the common atmospheric gases, melting of the metal presents numerous problems. It is necessary to provide an inert atmosphere in the furnace as well as a crucible material that will not react with the molten metal, if a ductile ingot is to be produced. Two special furnaces have been developed that meet the requirements and one, the induction heated graphite furnace, has been described in some detail.<sup>1</sup> Little information is available for sizable units wherein power is applied to the melt through an arc, and the dearth of technical information on such a furnace prompted this report. It has been demonstrated clearly that arc melting produces titanium metal with superior toughness, ductility, and formability. To produce titanium ingots with these properties, an automatic, continuous casting arc furnace has been developed and is described herein.

Discussion on this paper, TP 3087D, may be sent, 2 copies, to AIME by Oct. 1, 1951. Manuscript, Feb. 7, 1951. St. Louis Meeting, February 1951.

The history of arc melting may be traced to 1800, when Sir Humphrey Davy<sup>2</sup> first experimented with Volta's electric battery and found that light could be produced and an arc formed between two carbon points attached to the cell. The discovery of the arc was followed by the design and construction of an arc furnace by Napier,<sup>3</sup> in 1845, for the reduction of metal oxides. In 1853, Pichou<sup>4</sup> described a similar furnace, although it was not until the discovery of the dynamo in 1867 that the arc furnace could achieve commercial significance. In 1878, Siemens<sup>5</sup> designed the first arc furnace intended for the melting of metals and by 1882 had melted steel and platinum successfully.

This was followed by Moissan's<sup>6</sup> classical work with the arc furnace in 1892. W. von Bolton,<sup>7</sup> in 1905, found that the arc furnace was suited admirably for melting refractory metals. In his work with tantalum, no suitable refractories for retaining the molten metal were found to exist. Together with Otto Simpson, he developed an arc furnace with a water-cooled copper crucible in which tantalum could be melted without contamination. This technique proved eminently successful.

In his paper on the preparation of ductile titanium, Kroll<sup>8</sup> first described an application of the von Bolton furnace to the melting of this metal. The

The basic principles developed by von Bolton have been applied with increasing frequency in recent years for melting refractory and highly reactive metals on a laboratory and commercial scale. Parke and Ham<sup>9</sup> described a very interesting furnace for arc melting molybdenum, and Eastwood, Simmons, et al.<sup>10</sup> employed the arc furnace in their preparation and study of titanium alloys.

In the development of an arc furnace for melting titanium, a manually operated pilot model was constructed first. From this unit, techniques for feeding titanium sponge, characteristics of inert atmospheres, and the consumption rates of various types of electrode materials were determined. It was found that crushed titanium sponge could be fed at a controllable rate to the furnace chamber by means of a vibratory feeder either continuously or at desired intervals. An atmosphere of argon or helium proved to be satisfactory for manual as well as automatic melting procedures.

During initial runs of the manually operated furnace, it was found that the ingot could be removed continuously at the same rate as sponge was melted in the furnace. Operating at a slight positive internal pressure, it was possible to maintain an effective seal between the ingot and the crucible wall. If a leak occurred, the inert atmosphere bleeding outward prevented the ingress of air.

With the above data available, the furnace illustrated in Fig. 1 was designed and constructed. The furnace proper is entirely water-jacketed, including the crucible, furnace neck, furnace head, and electrode assembly. An auxiliary pump circulates water through the system, the major portion of which is recycled. The ingot, 5¾ in. in diam, may be cast continuously by retracting it at a uniform rate by means of a hydraulic ram. Because of the desirability of having a rugged crucible that could stand constant use without frequent replacement, thin-walled copper crucible sleeves were replaced with extra heavy sleeves of copper pipe. This latter type of crucible has proved very satisfactory.

top of the furnace through the head to the ingot surface. This shaft, rotated by a motor mounted on the electrode support, revolves an offset electrode holder and permits the electrode to cover the surface of the molten pool. Any variation in the potential across the arc actuates the racking motor which automatically raises or lowers the electrode to regain the desired operating voltage. By such a technique, constant power input to the melt is maintained.

## Operation and Scope

AUGUST 1951, JOURNAL OF METALS—621

Fig. 2—Titanium ingots up to about 60 in. are continuously cast from the furnace.

thrown in. The electrode, based upon a pre-set voltage, is lowered automatically to strike an arc. After the arc is struck, the electrode rises until the desired potential is attained. The electrode, driven by the rotor motor, begins to rotate and move the arc over the ingot surface.

When the surface of the stub ingot becomes molten, the feeder switch is turned on and in each rotation of the electrode, sponge is fed into the crucible.

As soon as the feed is started, the ingot retractor is set in motion, and the speed of ingot withdrawal is adjusted to conform to the rate of sponge feed. After these manipulations are carried out by the furnace operator, no further work is required of him, except to check the furnace controls. Should the arc be broken for any reason, the control mechanism automatically restrikes the arc. Thus after the furnace is started, the melt is carried out completely automatically.

Commercially pure sponge can be melted at a rate of 0.6 to 1.0 lb per min with a power input of 64 to 100 kw. Alloys can be melted at an even higher rate, provided that they have a lower melting point than pure titanium.

The furnace operation is believed safe. Should the crucible be burned through for any reason, the pressure developed by the steam generated would break either the large rupture disk in the feed hopper or in the furnace head. At the same time, the vapor formed would extinguish the arc and open the electrical circuit.

Two furnaces of this type are now in operation. They have demonstrated the feasibility of this basic design and are paving the way for large-scale automatic, continuous casting furnaces. In addition to casting titanium, this type of furnace could be employed for other metals whose reactivity requires the use of an inert atmosphere and a chemically inert crucible.

Alloys of titanium as well as pure titanium can be melted in this furnace. Sponge of relatively uniform particle size usually is tumbled with the powdered alloying elements in an inert atmosphere. After blending, the alloying powders fill the interstices of the sponge and leave little if any residual powder in the blender. If metal powders are not used, the alloying metals should be screened to a relatively uniform size before blending with the sponge. This method has been used successfully for a variety of alloys. A continuously cast ingot 4 ft 5 in. in length and scalped to a depth of  $\frac{1}{4}$  in. on the diameter is shown in Fig. 2.

Although this discussion has been limited primarily to an arc furnace of the nonconsumable electrode type, it has been shown to be feasible to melt titanium as a consumable electrode. The basic furnace described herein need be modified only slightly to accomplish this end.

### Characteristics of Ingots

If arc-melted ingots are allowed to cool to room temperature before being removed from the furnace,

Fig. 3—This shows the top of a typical ingot produced by arc melting. It is in the as-cast condition, enlarged 2X. This ingot is actually  $5\frac{3}{4}$  in. diam, but a reduction in size was necessary to reproduce the photograph.

the top of the ingot appears as a bright, shiny surface with the grain boundaries clearly delineated. The top of a typical ingot is shown in Fig. 3. When a hot ingot is removed from the furnace, a thin oxide film is formed on the entire ingot surface. The oxide film formed on continuously cast ingots is very thin and is not considered objectionable. For this reason, and the fact that all subsequent hot-working of the ingot is done in air, no effort has been made to prevent oxide film formation during the continuous casting operation. The side of the ingot presents a slightly rippled surface, Fig. 4. This ingot was furnace-cooled and presents a bright metallic surface. To produce a void-free surface, it usually is necessary to remove from  $\frac{1}{8}$  to  $\frac{1}{4}$  in. on the diameter. Any minor voids which then appear at the surface can be removed readily by surface grinding. After the above operations, the ingot is ready for forging.

Although Fig. 3 indicates that the grains might possibly be equiaxed and of relatively uniform size, such is not the case. Several ingots have been cross-sectioned to determine the longitudinal grain configuration. These ingots, as typified by the ingot shown in Fig. 5, have long grains growing from the bottom of the ingot toward the top. Grains up to 10 in. long have been noted. Small, preferentially oriented grains are found at the mold surfaces. In general, the structure of arc-melted material is typical of that obtained in chill-case ingots. The ingots as-cast are usually sound and free from extensive porosity. It has been found that internal pores which may occur in arc-melted ingots seal up readily when the ingot is forged, while external defects usually result in cracking.

Fig. 4—The surface of an as-cast ingot is relatively in good condition, as shown in this  $1\frac{1}{2}$  diam enlargement.

Fig. 5—An as-cast arc-melted ingot etched with HF-HNO<sub>3</sub> shows columnar grain structure. X3.

Despite the fact that the feed metal is contaminated to the extent of about 0.2 pct by the graphite electrode employed during melting, this is virtually the only contaminant added to the melt. In batch melting, a static sealed inert atmosphere is employed which, if gettered by passing over hot titanium sponge, will reduce the contamination by oxygen and nitrogen to trace amounts. In continuous casting, nitrogen contamination can be held at virtually the same level if gettered gas is employed, since the rate of flow of helium required to maintain a slight positive pressure in the furnace is only of the order of 0.5 cfm. With the exception of an arc furnace em-

playing a consumable titanium electrode, the non-consumable electrode technique produces titanium ingots of the highest purity.

### Properties of Arc-Melted Titanium

The physical properties of arc-melted titanium of commercial purity are intermediate between those of high purity titanium made by the iodide process and induction-melted metal. Arc-melted titanium shows much higher strength than iodide titanium and can be rolled readily to thin sheets that can be fabricated by standard techniques. While induction-melted titanium containing 0.4 pct C and above has slightly higher strength, sheet rolled from this material shows lower formability and requires larger bend radii. In addition, the toughness of induction-melted material, as indicated by Charpy V-notch impact tests, is only half that of arc-melted titanium. A tabulation of typical physical properties of arc-melted, induction-melted, and iodide titanium is presented in Table I. The microstructure of sheet rolled from arc-melted titanium is typified by that shown in Fig. 6.

The microstructure of annealed, arc-melted titanium sheet shows a matrix of irregularly shaped grains of  $\alpha$  titanium. Carbides usually are present in relief because of their high hardness. There are also a number of small dark etching particles which seem quite numerous for a metal with less than 1 pct of impurities. The exact nature of these dark etching particles has not been determined.

Arc-melted titanium is preferred for the production of sheet metal as the higher purity results in material with greater ductility and formability. Annealed sheet with an 0.2 pct offset yield strength of 80,000 psi can be bent around a mandrel with a radius that is only double the sheet thickness. The ductility of titanium is restricted by its hexagonal structure, and at room temperature titanium deforms by slip along the basal planes of the crystals. The additional work performed during rolling, as compared to a bar that is only forged, seems to improve the ductility of the finished sheet.

Impact tests of arc-melted titanium show breaking strengths almost double those for induction-melted metal. Values listed in Table I were for small ingots forged to ½ in. square bars.

From the data presented in Table I, it may be seen clearly that arc-melted titanium has higher form-

ability and toughness than induction-melted metal containing carbon above 0.4 pct. For end uses where these properties are required, it will be necessary to melt sponge titanium by arc melting or similar techniques, hence, the need for developing arc-melting know-how.

### Summary

An automatic, continuous casting arc furnace employing a direct current arc has been constructed and operated successfully. While designed specifically for melting and casting titanium it can be employed for melting other reactive metals. Comparative properties of arc and induction-melted titanium indicate that where high ductility and formability and toughness are required, arc-melted material is preferable.

### Acknowledgment

The electrode mechanism and electrode control circuit of the arc furnace described herein were designed in conjunction with Mark F. Gouran, Philadelphia.

# Powder Metallurgy of Zirconium

by Henry H. Hausner, Herbert S. Kalish, and Roswell P. Angier

**P**OWDER metallurgical methods as applied to zirconium are of great interest because they permit not only the fabrication of parts directly to shape with a minimum loss of material but also the utilization of scrap, and the metal may be processed at temperatures well below the melting point. There are two difficulties involved in the melting of zirconium: 1—High vacuum is necessary for melting, and 2—zirconium reduces nearly all oxides so that it is difficult to find a suitable crucible material. The purest material, zirconium crystal bar, is expensive, and the methods of subsequent fabrication are limited. Cold rolling or extrusion of zirconium crystal bar is suitable for making certain shaped parts, but where melting is involved, the purity of the metal is invariably decreased, and a method of casting to a definite shape does not seem to be feasible.

Where it is necessary to hot roll, zirconium must be covered with a steel or copper jacket to protect it from the air. This is necessarily a costly operation. Where annealing of zirconium is necessary it must be conducted in a high vacuum.

H. H. HAUSNER, and H. S. KALISH, Members AIME, are Section Head and Senior Engineer, respectively, Metallurgical Laboratories, Sylvania Electric Products Inc., Bayside, L. I., N. Y. R. P. ANGIER, Member AIME, formerly with Sylvania Electric Products Inc., is now with North American Philips Co., Lewiston, Maine.

Discussion on this paper, TP 3101E, may be sent, 2 copies, to AIME by Oct. 1, 1951. Manuscript, Feb. 16, 1951. St. Louis Meeting, February 1951.

This work was done for the Atomic Energy Commission at the Metallurgical Laboratories, Sylvania Electric Products Inc.

In an investigation of powder metallurgical methods for zirconium, the zirconium powder used should be characterized by the following properties: 1—Highest degree of purity, 2—uniformity in particle shape and particle size distribution, 3—low compression ratio, and 4—satisfactory strength of the compacted powder (green strength). Zirconium powders have been made by two methods: By the reduction of zirconium tetrachloride ( $ZrCl_4$ ) with sodium,<sup>2, 4, 5</sup> and by the reduction of zirconium oxide with calcium and calcium chloride.<sup>6</sup> The first method represents one of the earliest attempts to make pure zirconium metal, and the sintered product from this powder is extremely brittle. The second method of making zirconium powder is far more successful, but the powder made in this way has an extremely low apparent density and, therefore, a high compression ratio which makes it difficult to use it for powder metallurgical purposes. For these reasons the above-mentioned zirconium powders were not used in this investigation. To obtain sintered zirconium compacts of highest purity and good ductility, it was first necessary to produce a suitable powder.

Pure zirconium has been made chiefly by two methods. The iodide method, from which the product is "crystal bar" zirconium, was developed first.<sup>1-3</sup> By this purification process very soft, pure, and ductile zirconium metal can be produced. The second method, developed by the U. S. Bureau of Mines, is the reduction of zirconium chloride with magnesium.<sup>8</sup> The sponge zirconium thus produced is also soft, pure, and ductile.

Fig. 1—Effect of compacting pressure on the pressed density of compacted zirconium and zirconium hydride powders.

There are, however, several distinct differences between zirconium produced by these two methods. The sponge metal must be melted and cast to make it suitable for subsequent fabrication, while the crystal bar can be directly rolled or extruded to the desired shape. Both methods yield metal with about 0.5 to 3.0 wt pct hafnium. The melted and cast sponge contains appreciable carbon, about 0.1 wt pct, and perhaps more oxygen and nitrogen than the crystal bar, but it is equally as pure in respect to other elements. Zirconium made from Bureau of Mines sponge is harder, somewhat lower in ductility, and higher in tensile strength than the crystal bar product. These differences may be attributed chiefly to the higher oxygen and carbon content of the zirconium sponge product, although it is not clear what role the carbon plays in affecting physical properties. In order to investigate the powder metallurgy of zirconium, powders made from zirconium crystal bar were used.

### Powder Preparation

**Processing:** Zirconium crystal bar is too ductile at room temperature and even at very low temperatures, such as that of liquid nitrogen, to be comminuted by mechanical methods. Zirconium, however, forms a hydride that is brittle enough to be comminuted mechanically, and the hydride powder then can be readily decomposed in vacuum. Therefore, the hydride method was chosen for the preparation of the powder.

Zirconium hydride forms in the temperature range from about 235° to 800°C.<sup>6</sup> The absorption of hydrogen, whether it goes into solid solution or forms the hydride or both, is most rapid at about 400°C. At this temperature, face-centered tetragonal ZrH<sub>2</sub> forms. Above this temperature ZrH<sub>2</sub> is no longer stable, and hydrogen will be given off, if the sample has been previously heated at 400°C until it has taken up enough hydrogen to form ZrH<sub>2</sub>. At about 800°C the face-centered cubic ZrH forms and can be retained if quenched to room temperature or cooled from this temperature in an inert gas or vacuum. If the ZrH is cooled slowly in hydrogen the formation of ZrH<sub>2</sub> will again occur in the vicinity of

400°C. Above 800°C hydrogen is given off until, at the transformation temperature of 862°C, there is a sudden absorption of hydrogen. Above this temperature hydrogen would again be given off. The mechanism of the formation of ZrH<sub>2</sub>, ZrH, and the solid solution of hydrogen in  $\alpha$  and  $\beta$  Zr is described in the literature.<sup>6-9</sup>

Zirconium hydride was made at 400° and 800°C for subsequent processing. The zirconium hydride made at 400°C was primarily ZrH<sub>2</sub>. At 800°C, ZrH formed, but furnace cooling in hydrogen permitted the formation of ZrH<sub>2</sub> to occur. X-ray analysis revealed that the product of the 800°C treatment was a mixture of ZrH and ZrH<sub>2</sub>, but contained a larger proportion of ZrH<sub>2</sub>. Subsequent to the hydriding process, the friable hydride pieces are ground by hand in a steel mortar with a steel pestle or in a hammer mill to the desired size. Both hydrides are so friable that they can be ground easily to pass a 400 mesh screen (0.037 mm) if that is desired. The product of the 400°C treatment appeared to be more friable, but it took somewhat more grinding to make it fine enough to pass through a 325 mesh screen.

The zirconium metal powder can be prepared by vacuum decomposition of a powdered charge of either of the hydrides, ZrH<sub>2</sub> or ZrH. The decomposition occurs by heating the hydride up to a temperature of 800°C or above in a vacuum of 0.05 micron or better. During the heating operation of the cycle, the pressure of hydrogen in the vacuum system rises to more than 25 microns and then diminishes rapidly to its initial value after being heated for a certain time (depending upon the amount of the charge) at 800°C or above. The slow rate of heating, the fast pumping speed, and the temperature of approximately 800°C are considered critical to the removal of hydrogen to a few hundredths of a percent and the obtaining of a loosely sintered cake of zirconium that can be easily ground to a powder.

The particle size distribution, densities, and apparent densities of the powders obtained by these methods are shown in Table I. Zirconium hydride pulverizes more easily than the zirconium obtained by the decomposition of the hydride and, therefore, contains a larger amount of fine particles. Both powders, zirconium hydride as well as zirconium, contain traces of Al, Ca, Cu, Fe, Mg, Mn, and Si of

practically the same amount as found in the zirconium crystal bar from which the hydride was made. Chemical analysis revealed the presence of gaseous impurities, i. e. 0.2 to 0.4 pct O and 0.01 to 0.015 pct N. There was very little difference in the particle shape of the three kinds of powders, ZrH, ZrH<sub>2</sub>, and Zr. All particles were of angular shape, similar to most particles obtained by crushing.

**Equipment:** The equipment for the preparation of the hydride comprises a quartz tube electric furnace and a hydrogen purification train. Formation of zirconium hydride requires the use of highly purified hydrogen, if the purity of the powder is to be maintained. Tank hydrogen which is reported to contain 0.2 pct O and no other appreciable impurities, was passed over copper turnings at 600°C to catalyze the reaction between hydrogen and oxygen to form water. The water was removed by activated alumina (Lectrodryer). A furnace, containing calcium turnings at 700°C, was used to remove the last traces of oxygen, nitrogen, and water. This purified hydrogen was permitted to flow over the zirconium crystal bar during the entire processing of the zirconium hydride, including the heating and cooling cycles. The charge was maintained at a temperature of 400° or 800°C for 1 to 20 hr, depending on the amount of zirconium, and the furnace was cooled in the hydrogen flow.

The vacuum furnace (globar type) used for the decomposition of the hydride powder to zirconium powder contains a sillimanite furnace tube and comprises a compound model CVD Kinney pump and a Distillation Products MC-500 metal diffusion pump.

### Processing Methods

**Compacting of Zirconium and Zirconium Hydride Powders:** Both zirconium powder and zirconium hydride powder can be compacted without the use of a binder. The powders flow easily and the filling of the compacting die can be done without any difficulties. The powder within the die cavity is levelled as easily as any conventional commercial metal powder.

The compression ratio is defined as the ratio of the volume of a loose powder to the volume of the compact after application of a specified pressure.

Fig. 2—Green strength of compacted —200 mesh zirconium and zirconium hydride powders.

Fig. 3—Effect of BeO on zirconium at sintering temperatures. Microstructure of the interior of a zirconium bar packed in BeO powder and heated 4 hr at 1250°C in high vacuum. Polarized light. X250. Area reduced approximately 50 pct for reproduction.

This ratio is low for both powders, as mentioned above. When conventional pressures of 40 to 50 tons per sq in. (tsi) are applied, the compression ratio ranges between 2:1 to 2.5:1. Inasmuch as the compression ratio determines the height of the compacting die, the low compression ratio of zirconium and zirconium hydride powders is very favorable for the die design.

Fig. 1 shows the effect of the compacting pressure on the density of the compacts made from zirconium hydride and zirconium powder. The powders were pressed in a single-action die of 3/8x2 in. die cavity at pressures varying from 20 to 90 tsi. Higher densities of the compacts may be obtained by using double-action dies or by pressing samples with a more favorable ratio between pressing area and die-wall area. The application of 100 tsi compacting pressure resulted in slightly higher density, but some of the compacts, pressed at 100 tsi, showed indications of lamination.

To determine the relative green strength of this compacted material, zirconium powder, zirconium hydride powder, and a mixture of 50 pct zirconium and 50 pct zirconium hydride powders were pressed at 30 and 70 tsi. Three samples of each type of approximately 1/8x3/8x2 in. were compacted at each pressure in the above described rectangular, single-action die. The compacts were placed on semi-knife edge supports which were 1 in. apart and loaded transversely with a dead load suspended from a semi-knife edge. The load was increased constantly until the sample broke. The differences in modulus of rupture between samples of the same material compacted at the same pressure correlated the slight differences in density that occurred from sample to sample. The data are presented in Fig. 2. There is probably some deviation from a straight line particularly at higher pressures, but for the present correlation it seems adequate to present the data as shown. The green strength of compacted zirconium is approximately twice as high as the green strength of zirconium hydride compacts. The addition of zirconium powder to zirconium hydride powder increases the green strength of compacts made therefrom.

If the pressed compact were the ultimate product, zirconium powder would be clearly a more suitable material than zirconium hydride. It will be shown later, however, that to produce a sintered material of good density, zirconium hydride can be compacted

Fig. 4—Effect of compacting pressure on the sintered density of pressed and sintered zirconium and zirconium hydride powders, sintered in high vacua.

at even lower pressures than zirconium powder. In addition, many large thin briquettes, approximately  $\frac{1}{8} \times 2 \times 13$  in., of zirconium hydride have been pressed at pressures as low as 15 tsi without a single loss by breakage.

**Sintering of Zirconium and Zirconium Hydride:** The extreme affinity of zirconium for oxygen and nitrogen<sup>8, 10</sup> makes it necessary to sinter in either a very pure inert gas or in a high vacuum. Compacted zirconium powder was sintered in purified argon. Even though the tank argon was purified by hot copper turnings, a Lectrodryer, drying towers of phosphorous pentoxide and magnesium perchlorate, and hot uranium turnings, it was not pure enough for the sintering of zirconium. The last traces of nitrogen could not be removed completely from the argon by the hot uranium turnings, and the zirconium invariably picked up excessive nitrogen. Sintering in vacuum of the order of  $5 \times 10^{-5}$  mm Hg or better was carried out successfully at temperatures of 1300°C or less without any noticeable in-

crease in oxygen or nitrogen content. Vacuum sintering was also advantageous because compacted zirconium hydride powder could be sintered directly, thereby eliminating a step in the process. When compacted zirconium hydride powder was sintered in purified argon, the residual hydrogen content was always high, but vacuum sintering reduced the hydrogen content to that of the original crystal bar.

When a compact of zirconium hydride powder is heated in vacuum above 400°C, an appreciable decomposition of the hydride occurs that is closely related with a considerable increase of the mobility of the metallic atoms. The degree of mobility of the metallic atoms at the temperature of the decomposition corresponds to far higher temperatures than those at which the decomposition actually takes place. When the hydride is destroyed, the metallic atoms are at a certain state of unstability that leads to their increased mobility. Because of the high degree of mobility, the metal atoms will migrate until they have found positions corresponding to a minimum of free energy. This process causes a faster rate in sintering of the compacts made from zirconium hydride powder compared to the sintering rate of compacts made from metal powder.

In sintering it is frequently desirable to pack the compacts in a refractory powder in order to have samples of all shapes readily supported and separated during sintering. To investigate the possible use of a packing material, pieces of zirconium crystal bar were packed in different refractory oxides and heated to the sintering temperature of 1250°C in vacuum for 2 hr. X-ray analysis revealed that during sintering the zirconium reduced BeO, SiO<sub>2</sub>, and ZrO<sub>2</sub>, and became contaminated with oxygen and Be or Si. Fig. 3 shows the extent to which zirconium reacted with BeO. The interior of the crystal bar after being heated in BeO powder revealed the typical Zr-Be eutectic structure, as described previously,<sup>11</sup> characteristic of about 2 to 5 wt pct Be. Melting was, of course, evident in this sample by the appearance after the 1250°C treatment. The use of a packing medium of refractory was abandoned because it was expected that even if no reaction occurred the out-gassing of the refractory powder surrounding the zirconium would increase the gas content during sintering.

Stabilized zirconium oxide boats and slabs were used with some success for sintering since the contact with the refractory was not so intimate that much reduction of the ZrO<sub>2</sub> could occur. Even so, the

Fig. 5—Interface between zirconium and zirconium hydride. Zirconium hydride powder (shown after sintering on the bottom) placed in the die and pressed at 7 tsi. Zirconium powder (shown on top) added and the entire compact was pressed at 50 tsi. Sintered as indicated in high vacuum. a (left)—Sintered 2 hr at 1190°C. Bright field. b (center)—Sintered 2 hr at 1190°C. Polarized light. c (right)—Same sample as b. Resintered 2 hr at 1300°C. Polarized light. X100. Area reduced approximately 50 pct for reproduction.

reduction of the  $\text{ZrO}_2$  was a possible source of oxygen pickup, and the difficulty in obtaining large boats of stabilized zirconium oxide prompted a search for a better container for sintering.

It was found that samples in intimate contact with graphite did not pick up carbon. Graphite adhered to small areas of the resting surface of the sample, but the carbon penetration was never more than a few mils even after sintering at  $1390^\circ\text{C}$ . Samples sintered in a covered graphite boat and separated by graphite slabs had bright, shiny surfaces. Pieces of zirconium crystal bar revealed no oxygen or nitrogen pickup after being heated in these graphite boats for as long as 10 hr at  $1260^\circ\text{C}$  in a vacuum of about  $2 \times 10^{-5}$  mm. The excellent surface appearance, freedom from contamination, and ease of preparation of graphite boats and slabs of any size made the use of covered graphite boats the most desirable container for sintering zirconium.

In the discussion of the properties of sintered zirconium and other information on the powder metallurgy of zirconium, the powder used for compacting and sintering is zirconium hydride. It is essential, then, that the relative merits of pressed and sintered zirconium powder and zirconium hydride powder be discussed before eliminating the former in the general discussion.

Earlier unpublished work by Angier and Hausner clearly indicated that the sintered product of compacted zirconium hydride powder is superior in most respects to that of zirconium powder, i.e., the ductility, corrosion resistance, and gas content was more favorable in the former. Obviously these superior properties are a function of the lower oxygen and nitrogen content, the source of this added gas being in the extra pulverization step necessary to produce zirconium powder. Fig. 4 shows that compacted zirconium hydride sinters readily to the full density of zirconium and that it is comparatively insensitive to differences in compacting pressure in the range shown. In reality, then, if the full density of zirconium is to be obtained, zirconium hydride powder can be compacted at lower pressures than zirconium powder. The inferior green strength of compacted zirconium hydride powder is a small sacrifice for the other benefits obtained, especially since the green strength of these compacts pressed at practicable pressures is sufficient to make them easy to handle.

A test was made to determine if compacted zirconium powder could be pressed together with compacted zirconium hydride powder to give a good final bond during sintering. Such a process might have an application in making specialized shapes where the large shrinkage differential between the two types of compacted powders during sintering could be utilized. The process is indeed favorable. As shown in Fig. 5 an excellent bond was developed. This investigation proved, however, to be a more decisive indication of the superiority of zirconium hydride powder than could be determined by other tests. In Fig. 5a, b, and c, the sintered product of compacted zirconium powder is shown on the top and that of compacted zirconium hydride powder on the bottom of the micrographs. The zirconium hydride powder was pressed in a die at 7 tsi and zirconium powder was added, levelled, and the two layer compact pressed together at 50 tsi. The sample was then sintered in high vacuum for 2 hr at  $1190^\circ\text{C}$ . It is evident from Fig. 5a that the zirconium hydride powder yielded a much less porous sintered zirconium

Fig. 6—Effect of sintering time and compacting pressure on the sintered density of zirconium. Samples compacted from zirconium hydride powder and sintered in vacua at various temperatures.

than did the zirconium powder. Fig. 5b shows how the grain growth of the zirconium progressed.

Even though the original particle size of the zirconium hydride powder was much less than that of the zirconium powder, the sintered product of the former has a much coarser grain size. The sintered zirconium powder shows very little if any grain growth at this stage (2 hr at  $1190^\circ\text{C}$ ). However, as would be expected, the sintered zirconium of compacted zirconium hydride shows marked grain growth. In Fig. 5c the resintered sample shows the further progress of grain growth and densification. Evidently the decomposition of zirconium hydride during sintering yields a compact composed of particles that have extremely clean active surfaces ideal for bonding. Whatever the fundamental sintering mechanism may be these highly activated surfaces, then, are ideal for the sintering phenomenon to occur. It is interesting to note that many of the large pores which remain (Fig. 5a and b are identical fields) are within the grains and do not seem to act as barriers to grain growth. This test may be used as another proof that the sintering of compacted zirconium hydride powder may be carried out at lower sintering temperatures and shorter sintering times. There are, then, at least six factors which point to the direct use of zirconium hydride powder for pressing and sintering. These are: 1—Reduction in processing cost of the powder. 2—Reduction in time for processing the powder. 3—Better physical properties of the sintered compact because of lower gas content. 4—Less opportunity for the pickup of impurities during the various processing steps. 5—Permits the use of lower compacting pressure to attain ideal or any arbitrary density. 6—Permits the use of lower sintering temperature and shorter sintering time to attain the ideal or any arbitrary density.

*Hot Pressing of Zirconium Powder:* Tests were

made with pressing of zirconium powder at elevated temperatures. The pressing was done in a graphite-lined steel die at 650°C for 15 min in vacuum at a pressure of 25 tsi. Under these conditions the powder compacted to a solid mass to a density of 6.53 g per cc. The hot-pressed specimens showed uniform fine grain size slightly less than that of cold-pressed and subsequently sintered specimens of similar density. The hardness of the hot-pressed specimen was slightly higher than that of the corresponding cold-compacted and sintered sample.

### Properties of Sintered Zirconium

**Experimental Procedure:** The best processing methods as derived from information incorporated in the preceding sections were utilized to make a comprehensive study of the powder metallurgy of zirconium as processed under a set of standard conditions.

The zirconium hydride was formed at 800°C and ground in a steel mortar and pestle to pass through a 325 mesh screen. One batch of thoroughly blended powder was used for all the tests to be described subsequently thereby eliminating possible variables that may be introduced by variations in the powder.

The samples were compacted in a rectangular steel die 3x1/4 in. to a thickness of about 1/8 in., each sample containing a uniform charge of 7 g of zirconium hydride powder. The compacts were pressed at 35, 50, and 75 tsi, placed in a covered graphite boat, and separated by graphite slabs. The boat was placed in a vacuum furnace, evacuated for at least 16 hr and sintered at 990°, 1150°, 1260°, and 1390°C for 5 min, 1, 3, and 10 hr. During the heating of the specimens the pressure in the furnace tube increased at about 800°C due to decomposition of the zirconium hydride and did not begin to decrease until the temperature was about 950°C. The samples were furnace-cooled in vacuum.

The sintering was done in a global furnace containing a sillimanite tube. This tube was sealed to glass and the entire pumping system up to the mechanical pump was glass. The vacuum was generally about 2x10<sup>-5</sup> mm at temperature. The as-sintered samples had bright, clean, shiny surfaces.

**Densification of the Sintered Compact:** The ultimate

density of compacted and sintered zirconium was investigated as a function of the compacting pressure and sintering variables such as time and temperature. The powder was not varied as pointed out earlier. It is worthy of mention, however, that experiments with zirconium hydride powder ground to a particle size less fine than the —325 mesh did not densify during sintering as readily as the compacted —325 mesh powder at the same time and temperature.

In Fig. 6 the effect of compacting pressure, sintering time, and sintering temperature on the density of zirconium is shown. The role of compacting pressure becomes insignificant at the higher sintering temperatures and longer times. When a minimum of sintering time and the lowest possible temperature is desired, the use of higher pressure becomes important. Ideal density can be attained, for instance, by sintering 1 hr at 1150°C provided a compacting pressure of 75 tsi has been used.

Fig. 7 shows a plot of isodense lines after sintering at any time and temperature in the range shown for compacts pressed at 50 tsi. From this the density obtainable for any given sintering temperature and time can be predicted. The densities would vary, of course, to perhaps ±0.03 g per cu cm because of deviation in both measurement and sample. Compacts pressed at 50 tsi, however, can be sintered to full density as shown by the line for completion of densification. In order to better show the effect of compacting pressure on completion of densification, Fig. 8 is presented. If a sample is to be sintered to ideal density for 8 hr at 1250°C, compacting pressures as low as 35 tsi can be used. If the sintering temperature must be low, however, higher compacting pressures become necessary. At 1100°C, for instance, a sample which has been compacted at 75 tsi can be sintered for as little as 3 hr to attain ideal density.

**Grain Growth:** The grain growth of zirconium during sintering is very rapid provided the material charged to the sintering furnace was compacted zirconium hydride powder. In Fig. 9 the grain size of zirconium, sintered at various times and temperatures, is shown. The actual grain size is shown in microns and in grains per sq mm in Table II.

Fig. 7—Constant density lines as a function of sintering time and temperature for zirconium. Vacuum sintered from —325 mesh zirconium hydride powder compacted at 50 tsi.

Fig. 8—Isodense lines representing 6.59 g per cu cm (complete densification) for three compacting pressures. Data for —325 mesh zirconium hydride compacted as indicated and vacuum sintered.

Fig. 9—Effect of sintering time and temperature on the grain growth of zirconium. Compacts pressed at 50 tsi from —325 mesh zirconium hydride powder and sintered in vacuum. X250. Area reduced approximately 80 pct for reproduction.

It appears that grain growth is most rapid in the vicinity of 1100° to 1200°C. At 990°C the growth was quite slow compared to the rapid growth which occurred on sintering at more elevated temperatures. Densification, on the other hand, is relatively rapid at lower temperatures. The relationship between density and grain size is shown in Fig. 10. Initially in the sintering process considerable densification occurs with little grain growth. Toward the end of the sintering process the density becomes asymptotic to ideal and little densification occurs, but grain growth is quite rapid. The relationship between the sintering mechanism and grain boundary movement,

density. After sintering at higher temperatures, the effect of compacting pressure on the hardness becomes negligible. In fact, after a density of about 6.3 g per cu cm is reached, the hardness seems to become insensitive to the slight differences in density.

The hardness of dense sintered zirconium made by these methods is about Rockwell B 92. Variations in hardness may occur so that values from 90 to 94 Rockwell B are obtained. This deviation may be

Table II. Grain Size of Zirconium after Sintering

| Sintering Time | Grain Size, Microns |        |        |        | Grains per Sq Mm |        |        |        |
|----------------|---------------------|--------|--------|--------|------------------|--------|--------|--------|
|                | 990°C               | 1150°C | 1260°C | 1390°C | 990°C            | 1150°C | 1260°C | 1390°C |
| 5 min          | 21.8                | 49.7   | 69.4   | 117    | 2670             | 515    | 265    | 93     |

| 3 hr           | 31.2                | 107    | 128    | 119    | 1309             | 112    | 79     | 90     |
| 10 hr          | 51.6                | 139    | 143    | 152    | 480              | 66     | 63     | 55     |

if one exists, should have some interesting theoretical ramifications.

**Hardness:** The hardness of sintered zirconium may be influenced among other things by oxygen content, grain size, and density. The first two factors affect the intrinsic properties of the metal, but the hardness when affected by density is merely another indication of the amount of porosity.

In Fig. 11 the hardness is shown as a function of sintering time and compacting pressure for samples sintered at 990°C. It is clear that the only difference in the sintered product affected by compacting pressure is porosity. The differences in hardness, then, shown in Fig. 11, are representative of the trend in

Fig. 10—Relationship between grain size and density of sintered zirconium. Samples compacted at 50 tsi from zirconium hydride powder and sintered in high vacuum at various times and temperatures.

Fig. 11—Effect of compacting pressure and sintering time on the hardness of zirconium sintered in vacuum at 990°C from compacted —325 mesh zirconium hydride powder.

attributed to the variation in grain size and oxygen content, the former influencing lower hardness with more sintering because of grain growth and the latter influencing higher hardness with sintering at higher temperatures or for longer times. It is difficult to isolate the effect of these two variables on the hardness except at 1390°C where the increase in oxygen content noticeably increases the hardness, as shown in Table III. This effect is also clearly illustrated in both the experimental data on electrical resistivity shown in Fig. 12 and the schematic representation, Fig. 13.

Fig. 12—Electrical resistivity of sintered zirconium compacts pressed as indicated from zirconium hydride powder and sintered in vacuum at the times and temperatures shown.

Fig. 13—Idealized curves showing the probable effect of densification and of oxygen pickup during sintering on the electrical resistivity of sintered zirconium.

**Electrical Resistivity:** The electrical resistivity may reflect many variables operating in the processing of sintered zirconium. As explained in the sections on experimental procedure, the control of these experiments was such, however, that many variables can be eliminated from the discussion, and it is indicated that there are only three fundamental differences in the sintered compacts. These are: 1—Grain size, 2—oxygen content, and 3—density. It is probable that grain size would have little if any measurable effect on the resistivity. The two variables which need to be considered, then, are oxygen content and density. The pressed compacts to begin with have an oxygen content of about 0.2 wt pct, the main source of this oxygen being in pulverizing as has been described earlier. Little oxygen is picked up during sintering at temperatures up to 1260°C, but

Table III. Rockwell B Hardness of Sintered Zirconium. Samples Sintered in Vacuum from —325 Mesh Zirconium Hydride Powder Compacted at 50 tsi

| Sintering Time | Sintering Temperature, °C |      |      |      |
|----------------|---------------------------|------|------|------|
|                | 990                       | 1150 | 1260 | 1390 |
| 5 min          | 78                        | 88   | 90   | 95   |
| 1 hr           | 87                        | 93   | 91   | 95   |
| 3 hr           | 92                        | 93   | 92   | 97   |
| 10 hr          | 91                        | 91   | 95   | 98   |

there is some increase at the higher sintering temperatures and very long sintering times. This oxygen which is undoubtedly in solid solution after sintering would have a marked influence on the resistivity.

The electrical resistivity was measured for all sintered samples and these data are shown in Fig. 12. It is immediately apparent that the resistivity first decreases with sintering temperature and then increases. The decrease is definitely due to densification and the increase probably to oxygen pickup. This is shown in the schematic representation in Fig. 13. The resistivity, then, is a splendid guide to optimum sintering conditions, a minimum resistivity

Fig. 14—Microstructure of cold worked and annealed zirconium. Compacted from —325 mesh zirconium hydride powder and sintered 3 hr at 1260°C in high vacuum. a (left)—As sintered. b (center)—Cold rolled 75 pct reduction in thickness, longitudinal section. c (right)—Same as b but annealed 1 hr at 900°C. Polarized light. X200. Area reduced approximately 50 pct for reproduction.

indicating the optimum. From Fig. 12 it appears that the best sintering temperature is in the range 1150° to 1260°C. The data are insufficient to pick a value and establish this as the exact sintering cycle, but a useful sintering range can be ascertained. Compacting pressure plays a role, but the limits on compacting pressure are wide if the selected sintering range is 3 to 10 hr at 1150°C and 1 to 10 hr at 1260°C. This is in agreement with data on the other properties investigated. Samples sintered in these ranges had good density, relatively low hardness, and relatively low oxygen content.

The electrical resistivity of pure zirconium is reported<sup>12-13</sup> to be from 39 to 41 microhm-cm at 0°C, which corresponds to about 40 to 42 microhm-cm at room temperature. The lowest resistivity found in this investigation for sintered zirconium was 58 to 60 microhm-cm at room temperature. The difference between this and the reported electrical resistivity can probably be attributed to the higher oxygen content in the sintered product, which oxygen pickup has occurred during powdering of the zirconium hydride.

**Ductility:** Although tensile tests were not made, cold rolling permitted an evaluation of the ductility of the sintered zirconium. The sintered samples were cold rolled about 5 pct per pass, examined carefully for edge cracking after each pass, and rolling continued until the first sign of edge cracking. Treatment, i.e., compacting pressure, sintering time, and temperature, seemed to have no significant effect on the ductility, practically regardless of the density. In 50 samples of various densities that were cold rolled, the range in reduction of thickness to the first sign of edge cracking was 53 to 72 pct. The average reduction in thickness was 62 pct. The sintered zirconium, then, is quite ductile.

Fig. 14 shows the microstructure of zirconium. These rolling studies proved the existence of a high degree of ductility in sintered zirconium, which makes the powder metallurgy method of manufacturing zirconium parts most valuable.

### Conclusions

Zirconium of high purity can be fabricated by powder metallurgy methods. The use of zirconium hydride powder for compacting and sintering leads to a more superior product than does the use of zirconium powder.

The pressing and sintering conditions that permit the powder metallurgical fabrication of sintered zirconium are established. Compacting at conventional pressure of 40 to 50 tsi, sintering in vacuum within

the temperature range 1150° to 1260°C, and the use of covered graphite boats, during sintering, results in sintered zirconium compacts of practically theoretical density and appreciable ductility.

The superiority of zirconium hydride powder over zirconium powder is shown clearly. It should be useful to determine how well other metal compound powders, such as hydrides, oxides, and others, can be decomposed during sintering and whether this decomposition facilitates the sintering process. Further studies in these directions are under consideration.

### Acknowledgments

We wish to thank H. W. Woods and Eleanor Polukis for their preparation of metallographic specimens, N. P. Pinto for hot pressing studies, H. Mansfield for physical properties testing, and H. B. Michaelson for editorial work. We are particularly indebted to W. E. Kingston for numerous valuable discussions and suggestions regarding this work.

# Production of Aluminum

from

## Kalunite Alumina

by Arthur Fleischer and Julian Glasser

THIS country was faced with the possible necessity of utilizing nonbauxitic ores for producing aluminum during World War II. Construction of four experimental plants to treat such ores by four different processes was authorized<sup>1-4</sup> including one at Salt Lake City, for the conversion of Marysvale alunite to metal-grade alumina and potassium sulphate by the Kalunite process.<sup>4</sup> An aluminum reduction plant in Tacoma, Wash., with a capacity of 50 tons of aluminum per day, was constructed to handle the Kalunite alumina produced at the Salt Lake City plant. The alumina and aluminum plants were Defense Plant Corp. projects operated by Kalunite, Inc. and Olin Industries, Inc., respectively.

Kalunite alumina differs from Bayer alumina in several respects, particularly in that the former contains potash instead of soda. The presence of potassium in the alumina feed to the cryolite bath was stated by aluminum technologists to be undesirable under the usual operating conditions of

aluminum furnaces. In 1940, about 20 tons of Kalunite alumina produced in the Kalunite pilot plant, were reduced electrolytically in a 10,000 amp furnace at Battelle Memorial Institute and at the aluminum reduction plant at Neuhausen, Switzerland. These relatively small scale tests indicated that satisfactory commercial aluminum could be produced in a practical manner.

The Tacoma plant reduced about 2,500,000 lb of Kalunite alumina to produce more than 1,200,000 lb of aluminum, in accordance with the accepted practice for reducing Bayer alumina. It was desired to determine whether commercial aluminum could be produced on a large scale and to establish the technological differences in commercial reduction practice between Kalunite and Bayer alumina. In the course of collecting data, the effects of the abnormal chemical composition and physical properties of Kalunite alumina were observed wherever possible.

### Tacoma Reduction Plant

The reduction plant had two pot lines, each with 120 cells in series, operated at approximately 32,000 amp. Each cell was provided with a single rectangular Soederberg continuous anode, with side-pin electrical contacts. Each cell was hooded and ventilated through a stack connected to 14 other cells, with 25,000 cfm blower. When the plant started operation in 1942, all of the cathode linings were of block construction. Rebuilt cells were of rammed paste construction.

GLASSER, Member AIME, formerly Chief Chemist, Aluminum Division, Olin Industries, Inc., Tacoma, Wash., is now with Armour Research Foundation of Illinois Institute of Technology, Chicago.

Discussion on this paper, TP 3088D, may be sent, 2 copies, to AIME by Oct. 1, 1951. Manuscript, Feb. 17, 1950; revision, March 28, 1951. New York Meeting, February 1950.

Paper published by permission of Olin Industries, Inc. and Kalunite, Inc., East Alton, Ill.

A total of 12 cells in pot room No. 1 were operated on Kalunite alumina over a period of 17 months. The remainder of the plant operated on Bayer alumina. Shutdowns immediately after the war brought an abrupt halt to operations.

Operating Conditions

The average charge of alumina was 240 lb to a 9000-lb bath with an average of 3.5 to 3.8 anode effects per day. Normal operating voltage was maintained at 4.9 v and each anode effect (30 to 40 v) averaged 6 min. The crust on alternate sides and both ends of a pot was broken through at anode effects. Before placing a new charge of alumina on the exposed electrolyte, the space between anode and cathode was raked thoroughly. During normal operations, four gas holes, about 6 in. from the anode, were maintained in the crust. Surface temperature of the electrolyte was about 950°C. The ratio of NaF to AlF<sub>3</sub> in the bath was maintained between 1.45 and 1.50. The alumina content in the bath varied between 2 and 7 pct. Anode paste, prepared on the side, was loaded at the rate of about 5000 lb every 15 days. Each pot was tapped every third day, leaving 2 in. of metal pad after each tap.

Since only a small part of the reduction plant was operated on Kalunite alumina, special procedures were required in order to obtain accurate data. Ordinarily, raw material consumption, production, and power data are obtained from overall plant inventories and meter readings from the rectifier station. However, information on a small number of pots cannot be obtained in this manner. Therefore, it was necessary to record weights of all raw materials charged, weight of metal tapped, and voltages for each individual pot operating on Kalunite alumina. To compare the operation with Bayer alumina on the same basis, a section of eight pots was started approximately at the same time and operated for several months, with four each on Bayer and on Kalunite alumina, following identical processing and control procedures.

Each pot was tapped singly with return of all scrap metal to the pot. Total production was obtained from the weight of the as-cast metal. Metal was sampled prior to pouring and analyzed by wet and spectrographic methods. Alumina for each charge was weighed in 60 to 80-lb lots. Each carload of alumina was sampled and analyzed by wet methods. Cryolite and aluminum fluoride were measured from 100-lb sacks. The quantity of anode paste consumed was determined by weights of coke and pitch mixed in the paste plant. Ampere-hours, used for calculating current efficiency and power input, were very accurately measured by the line ampere hour meter. Voltages at each pot were recorded hourly, and voltage and time were recorded for anode effects. A time-weighted average of voltage was used for power input.

Raw Materials

Natural Greenland cryolite, aluminum fluoride, fluorspar, Bayer alumina, calcined petroleum coke for anodes, soft anode pitch, and cathode paste or blocks were purchased on specifications generally

\* The particle size refers here to the aggregates that persist on handling the alumina on the screens. Comparative X-ray diffraction patterns of Kalunite and Bayer aluminas made in 1940 showed that the primary crystallite sizes are the same; diffraction line breadths and intensities agreed very closely. The difference in particle (grain) sizes is to be attributed to the types of aggregation encountered in the two aluminas.

Fig. 1—Potash buildup in electrolyte, pot 95, starting Aug. 13, 1944.

acceptable for aluminum reduction. Typical chemical composition and physical properties of Kalunite and Bayer aluminas are summarized in Table I.

The average chemical composition of the Kalunite alumina showed higher silica, iron oxide, titania, and lead than Bayer alumina. Phosphorous pentoxide, potash and sulphur trioxide were also present in Kalunite alumina in appreciable quantities; but calcium oxide and soda, present in Bayer alumina, were not found in Kalunite alumina. Ignition loss and water absorption were comparable for the two aluminas.

Particle size distribution\* was not nearly so uniform for Kalunite alumina as it was for Bayer alumina. Excessive quantities of both coarse and fine sizing were present.

The uniformity in composition of the Kalunite alumina was poor. For 17 carloads of alumina, sulphur trioxide (SO<sub>3</sub>) varied from 0.40 to 2.30 pct, potash (K<sub>2</sub>O) from 0.25 to 0.78 pct, phosphorus pentoxide (P<sub>2</sub>O<sub>5</sub>) from 0.01 to 0.08 pct, iron oxide (Fe<sub>2</sub>O<sub>3</sub>) from 0.08 to 0.14 pct, and silica (SiO<sub>2</sub>) from 0.03 to 0.24 pct. This variability in the impurities

was due mainly to unsatisfactory operating conditions and difficulties encountered in the operation of the Salt Lake alumina plant, inflicting the penalties of low capacity operation. The quality of the alumina was lower than that of alumina produced experimentally from alunite ores in laboratory and pilot plant studies.

### Results of Reduction

**Quality of Metal:** Acceptable commercial grades of pig aluminum were produced. In the first half of 1945, 50 pct of the metal produced from Kalunite alumina was 99.60 pct metal (grade B) or better; 4 pct was 2A grade, 99.70 pct metal. To obtain higher grade metal it would be necessary to reduce the impurities in the alumina.

**Operating Record:** The overall operating record for all pots operating on Kalunite alumina showed that commercial alumina could be produced on a large scale without very serious handicaps in production, raw material consumption, and power input. No obnoxious fumes were emitted from the pots, either during normal operation or while breaking in the crust. However, difficulty was experienced in handling the Kalunite alumina, because it was not so free-flowing.

**Effect of Particle Size:** The coarse grain size contained in Kalunite alumina was undoubtedly the most serious factor in disturbing smooth pot operation.\*\* This also masked effects of other abnormal properties of Kalunite alumina. The excessive fine particles caused dust losses. Both the coarse and fine particles were probably responsible for adverse temperature distribution in the pots. The coarse, settling to the cathode bottom, and the fines, acting as a poorer insulator over the crust, would tend to make the bottom hotter. For efficient operation, the cathode should be considerably colder than the anode.

**Potash in Electrolyte:** Of the abnormal impurities in Kalunite alumina, potash appeared to be the only one that was retained in the electrolyte to any appreciable extent. Usually, the potash reached a maximum concentration between 1 and 3 pct in

about six weeks. Apparently a steady state condition was reached whereby the charging and volatilization losses were essentially equal. Fig. 1 illustrates typical data obtained during the operation of one of the cells. The upper limit of potash content of the bath is of the same order of magnitude as previously found in the operation of the 10,000 amp cell at Battelle Memorial Institute during 1940.

**Cathode Lining:** No particular adverse effects were noted on cathode linings. The absorption of potash in the lining was about the same as found for the absorption of soda from Bayer alumina.

**Comparative Reduction Data:** The data have been summarized in Table II. The Kalunite alumina used for comparative reduction data was screened to eliminate most of the excess coarse sizing. As compared to equivalent operation on Bayer alumina, the metal produced contained somewhat higher quantities of silicon, iron, titanium, and lead. Alumina consumed was about 13 pct higher than for Bayer alumina, mostly because of dust losses. No aluminum fluoride was required for the Kalunite alumina operation, because the potash did not continually build up in the bath. The higher rate of carbon dusting from the anodes is reflected in anode paste consumptions and skimmings removed. The current efficiency for pots operating on Kalunite alumina was about 10 pct lower than for those on Bayer alumina.† This caused higher energy input per pound of metal for pots operating on Kalunite alumina. Miscellaneous differences in operating characteristics for pots operating on Kalunite alumina as compared to those on Bayer alumina included lower anode effect voltages, lower bath surface temperatures, less potent anode gas flames, less serious anode corrosion, and less movement of the electrolyte.

**Pot Life:** The life of pots charged with Kalunite alumina appeared comparable to those charged with Bayer alumina. As an example, four pots were started on Kalunite alumina and at approximately the same time ten pots were started on Bayer alumina in pot room No. 1. They averaged 238 and 233 days of operation, respectively.

### Summary and Conclusions

The reduction of Kalunite alumina has produced commercially acceptable metal on a fairly large scale. While the operating record was not as favorable as for Bayer alumina, particularly with respect to current efficiency, it would appear that the operation will be controlled by economic conditions rather than technological consideration. Adverse effects of particle size were definitely confirmed. Improvement of the quality of Kalunite alumina with respect to chemical and physical properties, and/or modifying the electrolytic treatment will undoubtedly improve the reduction operation.

† The 10,000 amp cell operated at Battelle Memorial Institute showed a current efficiency of 85 pct.

# Intermetallic Compounds in the System Molybdenum-Beryllium

by Samuel G. Gordon, James A. McGurty, Gilbert E. Klein,  
and Walter J. Koshuba

ONE of the problems encountered in working with metals at elevated temperatures is the instability resulting from solid-solid diffusion at a common interface. A determination of the nature and magnitude of this phenomenon is important as related to structural properties of materials potentially useful in high temperature applications. This paper is concerned with the solid state reaction between metallic molybdenum and beryllium at elevated temperatures.

In the older literature,<sup>1</sup> there were no known intermetallic compounds in the system Be-Mo, and the list of beryllium intermetallics was rather small. New compilations have been made by Smithells<sup>2</sup> and by Taylor,<sup>3</sup> listing all the then known beryllium binary intermetallic compounds. In addition to these, some new phases have just been reported<sup>4</sup> in the system Zr-Be and some further compounds of the type  $\text{MBe}_{13}$  have been currently described.<sup>5</sup> The new compound  $\text{MoBe}_{13}$  which is reported upon in this paper differs considerably from the above mentioned  $\text{MBe}_{13}$  group, and will be discussed in detail.

## Diffusion Study

The nature of the solid diffusion at a Mo-Be interface was determined by sealing a beryllium rod inside a molybdenum capsule and heating at a temperature of 2000°F (1100°C) for 100 hr. The molybdenum capsule was fabricated from  $\frac{5}{8}$  in. swaged molybdenum rod obtained from the Fansteel Metallurgical Corp. The beryllium metal was obtained from Brush Beryllium Corp. as  $\frac{1}{4}$  in. cold-drawn rod. This material assayed 99.05 pct Be and contained as impurities 0.84 pct BeO and 0.19 pct  $\text{Be}_2\text{C}$ .

The molybdenum capsule was  $\frac{5}{8}$  in. in OD x 2 in. long. To prepare it, a concentric hole 0.250 in. + 0.001 in. — 0.000 in. in diam was drilled and reamed in one end of a rod to a depth of 1½ in. A 1 in. long beryllium rod 0.250 in. + 0.000 in. — 0.001 in. in diam was pressed into the molybdenum capsule. A molybdenum plug 0.250 in. ± 0.001 in. in diam x 9/16 in. long was then used to seal the beryllium in place. The capsules were placed in a molybdenum

Fig. 1— $\text{MoBe}_2$  and  $\text{MoBe}_{13}$  formed by solid-solid reaction between Mo and Be at 1100°C (2012°F), polished section at X250, unetched.

Fig. 2—Induction-heating melting assembly.

resistance furnace and heated at 2000°F (1100°C) for 100 hr. On cooling, the specimens were cut and examined metallographically. Fig. 1 is a micrograph at X250 of a portion of the interface from a transverse section. Four phases are clearly visible, with sharp boundaries between them. Phase A is a section of the molybdenum capsule; phase B is the molybdenum-rich intermetallic composition  $\text{MoBe}_2$ ; phase C is the beryllium-rich compound  $\text{MoBe}_{13}$ ; phase D is a section of the beryllium rod. All phases were readily polished to a high metallic luster.

The molybdenum-rich phase has a pronounced purple tinge. The beryllium-rich phase (C) is only slightly darker than the pure beryllium. In polarized reflected light, however, it shows striking birefringence between crossed Nicols. The black areas represent flaws or pores in the material. A small representative amount of powdered material from each of the phases was carefully removed under the microscope with a diamond tool. With this material, powder X-ray diffraction patterns were made for the identification of each phase. Table I lists the X-ray diffraction spacings and corresponding indexes characteristic of these intermetallic compounds.

## Synthesis

To establish the formula of the new intermetallic compound, X-ray diffraction patterns were made from powders obtained from solidified melts of known composition. The syntheses were made by

S. G. GORDON and G. E. KLEIN, formerly with Nepa Project, Fairchild Engine and Airplane Corp., are now with Los Alamos Scientific Laboratory, Los Alamos, N. M., and Oak Ridge National Laboratory, Oak Ridge, Tenn., respectively. J. A. MCGURTY and W. J. KOSHUBA, Member AIME, are with the Nepa Project, Fairchild Engine and Airplane Corp., Oak Ridge, Tenn.

Discussion on this paper, TP 3089E, may be sent, 2 copies, to AIME by Dec. 1, 1951. Manuscript, March 2, 1951; revision, June 4, 1951. Detroit Meeting, October 1951.

melting Mo-Be mixtures in various stoichiometric proportions.

A high purity molybdenum powder averaging 2 to 5 microns in particle size was obtained from the Fansteel Metallurgical Corp. A beryllium metal 200 mesh powder was obtained from the Brush Beryllium Corp. The material assayed 99.5 pct Be and contained as impurities 0.63 pct BeO, 0.12 pct Al, 0.12 pct Fe, and 0.04 pct Be<sub>3</sub>C. Powder mixtures of the two elements were ball milled in a rubber-lined mill using rubber-covered steel balls; the mixtures were then mechanically compressed at 100,000 psi into compacts which were approximately 2 in. long x 5/8 in. diam. These compacts were melted directly by induction. Fig. 2 is a schematic drawing of the melting assembly. A 20 kw Ajax induction unit permitted rapid heating to 3092° to 3272°F (1700° to 1800°C) in which temperature range all the compositions investigated were liquid.

On heating the unsintered compacts, an exothermic reaction was noted in the range 1472° to 1832°F (800° to 1000°C), due perhaps to a solid-solid reaction between the molybdenum and beryllium. The

liquid melt was held at a temperature of 3092° to 3272°F (1700° to 1800°C) for 10 min and then was allowed to cool in the crucible. The solid button readily separated from the crucible with little surface adherence. X-ray powder patterns were made of representative specimens from each melt. Comparison of these patterns with the standards for the two phases B and C showed that the composition corresponding to MoBe<sub>2</sub> was identifiable as the molybdenum-rich phase (B). The beryllium-rich phase was found to be MoBe<sub>13</sub>.

### Crystallographic Investigation

Well developed single crystals of the intermetallic compounds up to one millimeter in size were recovered from aggregates found in the ingots prepared for X-ray identification work. By careful mounting of these single crystals on a two-circle goniometer, oriented specimens were prepared suitable for use with a Weissenberg camera, using Ni-filtered Cu radiation ( $K\alpha = 1.5418\text{\AA}$ ) and with a precession X-ray camera. Measurements of the resulting X-ray diffraction patterns made possible the determination of unit cell constants of both intermetallic compounds. The density of single crystals of the relatively heavy MoBe<sub>2</sub> was measured by pycnometric methods using toluene. The density of MoBe<sub>13</sub> was measured using the float or sink method with Clerici solution and subsequently determining pycnometrically the density of the solution in which the crystal neither sinks nor floats.

MoBe<sub>2</sub>, the molybdenum-rich phase, occurred as parallel growths of tabular hexagonal crystals which showed the purple tinge characteristic of this phase. The unit cell constants determined from the diffraction pattern measurements are compared with values reported by Taylor<sup>2,6</sup> in Table II.

MoBe<sub>13</sub>, the new beryllium-rich phase occurred as aggregates of prismatic tetragonal crystals. Single crystal measurements yielded the following constants:  $a_0$ , 10.27Å;  $a_0\sqrt{2}$ , 14.52;  $c_0$ , 4.29Å;  $Z$ , 4;  $\rho$ , 3.13; and density, 3.13 g per cc. Since there were no systematic extinctions, the following space groups were possible: P42m, P4/m, or P42. Considerations of placing the 56 atoms (4 Mo and 52 Be) and of evidence obtained by Laue techniques indicate the space group P42 as being the most probable. The formula (MoBe<sub>13</sub>)<sub>4</sub> was calculated from the unit cell dimensions and the measured density.

### Conclusions

1—The existence of the intermetallic compound MoBe<sub>2</sub> has been verified. A table of the interplanar spacings of this compound is given.

2—A new intermetallic compound, MoBe<sub>13</sub>, is reported. This differs from other intermetallic compounds of the type MB<sub>13</sub> in being tetragonal instead of cubic. A table of the interplanar spacings of this compound is also included.

# Thermal Stability of The Chromium, Iron, and Tungsten Borides In Streaming Ammonia And The Existence of a New Tungsten Nitride

by R. Kiessling and Y. H. Liu

The chromium, iron, and tungsten borides have been treated with ammonia at different temperatures. They are attacked, forming metal nitride and boron nitride, and the results are summarized in the tables. In the tungsten-nitrogen system a new phase has been observed, closely related to the known  $\beta$  phase.

THE present investigations were begun to determine whether any ternary phases exist in the transition metal-boron-nitrogen systems for the metals chromium, iron, and tungsten. Attempts to prepare such phases were made by using the borides of the metals as starting materials and ammonia as the nitriding agent. Although no new ternary phases have been found to exist, the results may be of some interest with regard to the technical use of the borides.

## General Procedure

A steady stream of dry ammonia was passed through a silica reaction tube, the central part of which was kept at the reaction temperature while its ends were water-cooled. Weighed amounts of the borides were placed in a silica or porcelain boat and heated at different temperatures for a period of 10 to 24 hr. The boat was then rapidly removed from the reaction zone to the quenching zone, the water-cooled end of the tube, by means of a simple magnetic device. The nitrogen content of the products was determined by the increase in weight of the specimens, and the phase analysis was carried out by X-ray methods. For this analysis a Guinier-type camera, constructed at this Institute, was used with a bent, ground quartz crystal monochromator.

The general reaction, which occurred in all the experiments, may be summarized as:

For the higher temperatures pure metal was formed instead of metal nitride. It is sometimes difficult to

detect boron nitride among the reaction products by X-ray methods. Prolonged exposures of some specimens showed, however, that the strongest reflections of boron nitride were present. Additional evidence for its presence was given by the increase in weight of the specimens after nitriding. This increase was always greater than that corresponding to nitride formation only and was often in close agreement with the formula given above. Finally, a white powder, which was shown by X-ray methods to be boron nitride, was left if the reaction products after nitriding  $\text{Fe}_2\text{B}$  at  $448^\circ\text{C}$  and  $\text{FeB}$  at  $768^\circ\text{C}$  were dissolved in diluted sulphuric acid.

## Chromium-Boron-Nitrogen

Five phases have been found to exist in the Cr-B system,<sup>1, 2</sup> and all were used as starting materials. Investigations on the Cr-N system have shown the existence of two nitrides with ideal composition  $\text{Cr}_2\text{N}$  and  $\text{CrN}$ .<sup>3, 4</sup> The results are summarized in Table I. All the borides are attacked and decomposed into chromium nitride and boron nitride, and the kind of nitride formed depends only on the temperature and not on the boride used as starting material. The lowest reaction temperature, however, is different for the different borides. Thus the  $\delta$  phase begins to react at about  $735^\circ\text{C}$ , the  $\epsilon$  phase at about  $800^\circ$ , the  $\zeta$  phase at about  $900^\circ$ , the  $\eta$  phase

R. KIESSLING and Y. H. LIU are associated with the Institute of Chemistry, University of Uppsala, Uppsala, Sweden.

| 1100               |                                                |                                                |                                                | $(\text{Cr}_2\text{N}) + \text{BN}$    |                                   |
| 1180               | $\text{Cr}_2\text{N} + \text{BN}$              | $\text{Cr}_2\text{N} + \text{BN}$              | $\text{Cr}_2\text{N} + \text{BN}$              | $\text{Cr}_2\text{N} + \text{BN}$      | $\text{Cr}_2\text{N} + \text{BN}$ |

The lattice parameters found for the nitrides were:

$\text{CrN}$ :  $a = 4.150$  to  $4.145\text{\AA}$  (Blix;  $a = 4.148\text{\AA}$ )

$\text{Cr}_2\text{N}$ :  $a = 4.805$  to  $4.786$ ,  $c = 4.480$  to  $4.463\text{\AA}$ \*

(Eriksson:  $a = 4.806$  to  $4.760\text{\AA}$   
 $c = 4.479$  to  $4.438\text{\AA}$ )

No change in lattice parameters was observed for the borides.

\* Depending on temperature.

between  $900^\circ$  and  $1000^\circ$ , and the  $\theta$  phase at about  $1000^\circ\text{C}$ . It is of interest to note that this increase in stability bears a relationship to the crystal structures of the borides. The boron atoms in the  $\delta$  phase are only in contact with metal atoms, but not with any other boron atoms.\* The structure of the  $\epsilon$  phase is not known; but in the  $\zeta$  phase the boron atoms form chains; in the  $\eta$  phase, double chains; and in the  $\theta$  phase, hexagonal nets. The boron atoms thus form an increasing number of boron-boron bonds with increasing boron content of the phases, and the lower temperature limit where reaction occurs also seems to increase with the number of bonds. The dimensions of the chromium nitrides formed during the reactions are very similar to those reported in the literature, Table I. As the radius of boron is considerably greater than that of nitrogen this indicates that the nitrides formed do not contain any boron.

### Iron-Boron-Nitrogen

Both the  $\text{Fe-B}^{7,8}$  and the  $\text{Fe-N}^{7,8}$  systems have been investigated. The two iron borides,  $\text{Fe}_2\text{B}$  and  $\text{FeB}$ , were used as starting materials, and the results are summarized in Table II. The lowest temperature

The Greek letters denote the nitrides of iron according to Hägg's notation. The lattice parameters found for the different nitrides were:

$\zeta$ :  $a = 2.758$ ,  $b = 4.777$ ,  $c = 4.416$  (Jack:  $a = 2.763 - 2.761$ ,  
 $b = 4.828 - 4.830$ ,  
 $c = 4.425\text{\AA}$ )

$\epsilon$ :  $a = 2.714$  to  $2.748$ ,  $b = 4.701$  to  $4.760$ ,  $c = 4.381$  to  $4.409^*$   
(Jack:  $a = 2.764$ ,  
 $b = 4.787$ ,  
 $c = 4.420\text{\AA}$ )

$\gamma'$ :  $a = 3.789$  to  $3.795\text{\AA}$ \* (Jack:  $a = 3.794\text{\AA}$ )

$\alpha\text{Fe}$ :  $a = 2.867\text{\AA}$

No change in lattice parameters was observed for the borides.

\* Depending on temperature.

at which reaction occurs seems to be lower for  $\text{Fe}_2\text{B}$  (isolated boron atoms) than for  $\text{FeB}$  (boron chains). The products of the reaction are boron nitride and those iron nitrides which are stable in streaming ammonia at the reaction temperature. Thus the same tendency is shown by the iron borides as by the chromium borides. The borides seem to be more stable if the boron atoms are forming boron-boron bonds than if they are isolated, but the difference is not so marked in this system. The dimensions of the unit cells of the iron nitrides and iron formed in the reactions are in close agreement with those reported in the literature, Table II. Therefore the nitrides formed in this system do not seem to contain any boron either.

### Tungsten-Boron-Nitrogen

The three known tungsten borides<sup>9</sup> were used as starting materials. Investigations on the W-N system<sup>10</sup> have shown the existence of one nitride of probable composition  $\text{W}_2\text{N}$ , called the  $\beta$  phase. The results of nitriding are summarized in Table III. In specimens nitrided between  $825^\circ$  and  $875^\circ\text{C}$ , lines of a new phase appeared, which has not been described before. This phase was also found when pure tungsten was nitrided. It was called the  $\gamma$  phase in the W-N system and will be discussed below.

The marked increase in stability of the borides with increasing number of boron-boron bonds, which was noted for the chromium and the iron borides, is not found in this system. All of them begin to be attacked at temperatures between  $800^\circ$  and  $900^\circ\text{C}$ . The parameter of the cubic  $\beta$ -tungsten nitride was found to agree with that reported in the literature, indicating that the nitride is free from interstitial boron in the lattice.

### $\gamma$ Phase, Tungsten-Nitrogen

Earlier investigations on the W-N system have shown the existence of one tungsten nitride, slowly formed by nitriding tungsten with ammonia between  $700^\circ$  and  $800^\circ\text{C}$ .<sup>10</sup> It has not been possible to obtain this phase, called the  $\beta$  phase and assumed to have the composition  $\text{W}_2\text{N}$ , in a pure state. It

\* As a result of a renewed study of the  $\delta$  phase in the Cr-B system there is reason to suppose that it has the same structure as the  $\delta$  phase in the Mn-B system, where boron-boron contacts do not appear. In an earlier study,<sup>2</sup> one of the present authors (R. Kiessling) suggested that there is a slight difference between the structures of these two phases. This assumption was based on differences between rotation and Weissenberg photographs which seem to have been caused by twinning of the crystals of the Cr-B phase.

Table III. Phases Present After Nitriding of Tungsten and the Tungsten Borides in a Dry Ammonia Stream for 10 Hr. All Specimens Were Quenched from the Reaction Temperature.

| Temperature,<br>°C | Initial Tungsten Boride  |                                                  |                                    |                                                 |

$\beta$  and  $\gamma$  denote the known nitride "W<sub>2</sub>N" and the new nitride, respectively.  
The lattice parameters were found to be:  
 $\beta$  :  $a = 4.128\text{\AA}$  (Hägg :  $a = 4.126\text{\AA}$ )  
 $\gamma$  :  $a = 4.130$  to  $4.122\text{\AA}$   
 $\alpha$ W :  $a = 3.164\text{\AA}$   
No change in lattice parameters was observed for the borides.

\*Depending on nitriding temperature.

always appears mixed with tungsten. The crystal structure is that of a face-centered cubic metal lattice with four atoms in the unit cell and a parameter of  $a = 4.126\text{\AA}$ . On nitriding tungsten with ammonia at temperatures between 825° and 875°C, the quenched specimens showed lines of a new phase, called the  $\gamma$  phase by the present authors, Tables III and IV. Its lattice is probably closely related to that of the  $\beta$  phase, see below. The  $\gamma$  phase always appeared mixed with tungsten, and it was thus not possible to determine its nitrogen content. It probably has a composition close to that of the  $\beta$  phase (ideal composition W<sub>2</sub>N), as the increase in weight of tungsten was about the same when the  $\beta$  phase was formed as when the  $\gamma$  phase was formed (1.6 pct). Some heat treatments were carried out in order to study the thermal stability of the  $\gamma$  phase and the relationship between the  $\beta$  and  $\gamma$  phases. The  $\beta$  phase, formed at 750°C, was transformed to the  $\gamma$  phase on heating in a stream of ammonia at 850°C for 10 hr. The  $\gamma$  phase formed at 850°C was decomposed into tungsten and nitrogen on heating at 900°C in ammonia or in evacuated silica tubes. All attempts to transform the  $\gamma$  to the  $\beta$  phase, however, were unsuccessful. The  $\gamma$  phase was, for instance, heated at 700°, 760°, and 800°C for times up to 36 hr in streaming ammonia or at the same temperatures in evacuated silica tubes for times up to 24 hr, but no change was observed. It is thus impossible to decide from these experiments, whether the  $\gamma$  phase is a high temperature phase which transforms only very slowly to the  $\beta$  phase at lower temperatures, or a stable phase formed with the maximum velocity in streaming ammonia between 825° and 875°C, but the former possibility is the most probable.

X-ray investigations show that the  $\gamma$  phase gives reflections attributable to a simple cubic lattice. The length of the unit cell axis varies between the limits  $a = 4.130\text{\AA}$  at 825°C and  $a = 4.122\text{\AA}$  at 875°C, indicating an extended homogeneity range. All the reflections from a simple cubic lattice were present, but those with unmixed indexes were appreciably stronger than those with mixed indexes. This indicates a close relationship between the face-centered  $\beta$  phase, which only gives reflections with unmixed indexes and an axis of  $a = 4.126\text{\AA}$ , and this new  $\gamma$  phase.

The authors have assumed that the products after nitriding at 825° to 875°C consist of two phases,

tungsten and the new  $\gamma$  nitride. There is also a possibility that a mixture of three phases exists, namely tungsten,  $\gamma$  nitride, and  $\beta$  nitride, and that some of the reflections from the  $\beta$  and  $\gamma$  phases coincide. This assumption is not very probable, however, as all the reflections fit exactly into the same quadratic form. In addition, there is no indication of any extended homogeneity range of the  $\beta$  phase which would have to exist if some of the reflections of the  $\beta$  and  $\gamma$  phases were always to coincide. All the reflections from the nitride formed between 825° and 875°C therefore have been assumed to belong to one phase alone, the new  $\gamma$  phase.

The new reflections are much too strong to be considered as due only to an ordered distribution of the nitrogen atoms of the  $\beta$  phase. Consequently, the metal lattice must be deformed so that the face-centering disappears. Such a deformation may be caused by an ordering of the nitrogen atoms or by a change in the nitrogen content. The  $\gamma$  phase thus might be regarded as analogous to the  $\beta$  phase in the Mo-N° and the  $\delta$  phase in the Mn-N<sup>11</sup> systems. They are both high temperature phases, closely related to the face-centered cubic phases in the Mo-N ( $\gamma$ ) and Mn-N ( $\epsilon$ ) systems, respectively, and are formed by a tetragonal deformation of the face-centered metal lattices.

An attempt to determine the crystal structure of

the new phase was not successful. If it is assumed to have four tungsten atoms per unit cell, which is very probable because of the close correspondence in dimensions between the  $\beta$  and  $\gamma$  phase, and a simple cubic lattice, only the space groups  $Pm3$ ,  $P23$ ,  $Pm3m$ ,  $P43$ , and  $P43m$  are possible. Four metal atoms forming a noncentered lattice can only be placed in these space groups in the fourfold positions 4: (e) in  $P23$  and  $P43m$ . They both give the same arrangement with the coordinates  $xxx$ ;  $\bar{x}\bar{x}\bar{x}$ ;  $\bar{x}\bar{x}\bar{x}$ ;  $xxx$ . For  $x = 1/4$  a face-centered lattice is obtained, and from space considerations ( $r_w > 1.34$ ) it is easily seen that the limits for the parameter are  $0.23 < x < 0.27$ . A study of the structure factors shows that this arrangement is not in agreement with the observed intensities, Table V. The possibility of a cubic unit cell with an axis of  $a_1 = 2a$  or  $a_1 = 3a$  must be excluded as some observed lines then correspond to numbers in the quadratic form which are not sums of squares of integers (28 in the former case, 15, 39, and 60 in the latter). A unit cell with an axis of  $a_1 = 4a$  is again possible, however, and the indexes of this bigger cell are also given in Table IV. The probable space groups for this cell are  $Fm3c$ ,  $F43c$ ,  $Fm3$ , and  $F23$ . The structure of the metal lattice must be closely related to that formed by 64 face-centered cubic cells, each with  $a = 4.130$  to  $4.122\text{\AA}$  and four metal atoms per unit cell. It is possible to place 256 atoms in positions corresponding to such a structure in the space groups mentioned, but the task of varying the parameters in a systematic way to obtain a deformed structure giving the observed intensities is too difficult when only powder data are available.

The symmetry might also be tetragonal or still lower. No indication of splitting up the reflections was observed, however, and thus the ratio  $c/a$  must be equal or nearly equal to an integer. This case, although possible, is not very plausible.

The possibilities of a defect lattice with missing tungsten atoms or a lattice where tungsten atoms are replaced by nitrogen atoms are not conceivable.

Summing up the different possibilities discussed, the most probable, in the opinion of the authors, is a cubic cell containing 256 tungsten atoms with positions nearly corresponding to a cubic close-packing.

### Discussion

The present results indicate that the formation of boron nitride is a deceivable factor in the reaction:

Boron nitride is a very stable compound with a high melting point. Its lattice is similar to that of graphite, consisting of hexagonal nets where each boron atom within a net is in contact with three nitrogen atoms and each nitrogen atom with three

boron atoms. A B-N pair has the same number of electrons as two carbon atoms and the nets are probably formed by strong resonating B-N bonds. The fact that the stability of the chromium and iron borides in ammonia increases with increasing number of boron-boron contacts is of interest and supports the assumption that strong boron-boron bonds exist in the higher borides.

It is also of interest to note that the  $\delta$  phase in the Cr-B system is attacked at a considerably higher temperature than  $\text{Fe}_2\text{B}$ , and that the  $\zeta$  phase in the Cr-B system is more stable against attack than  $\text{FeB}$ . Although  $\delta$  Cr-B and  $\text{Fe}_2\text{B}$ , as well as  $\zeta$  Cr-B and  $\text{FeB}$ , are not isomorphous, their structures are closely related and the results consequently support the view that the strength of the metal-boron bond decreases with increasing atomic number of the transition element in the same period. This decrease has also been noted for the metal-hydrogen, metal-carbon, and metal-nitrogen bonds. The stability of hydrides, carbides, and nitrides decreases with increasing atomic number of the transition element in a period.

### Summary

The borides of chromium, iron, and tungsten have been treated with ammonia at different temperatures. They are all attacked and form metal nitride and boron nitride. For the chromium and iron borides, the stability in ammonia increases with increasing boron content, which supports the view that strong boron-boron bonds exist in the higher borides.

In the W-N system a new phase ( $\gamma$ ) has been observed. It is formed at nitriding temperatures between 825° and 875°C and is probably closely related to the already known  $\beta$  phase. All the reflections observed may be interpreted assuming a cubic cell with  $a = 4.130$  to  $4.122\text{\AA}$  (depending on nitriding temperature) and containing 4 tungsten atoms. There are reasons to assume that the real unit cell of this phase is cubic and contains 256 tungsten atoms (cube edge =  $4a$ ) in positions nearly corresponding to a cubic close-packing.

The investigations also support the view that the strength of the metal-boron bond decreases with increasing atomic number of the transition metal in the same period.

### Acknowledgment

The authors wish to thank Professor G. Hägg for valuable discussions. They also wish to thank S. Wahlgren for technical assistance. The investigation has been supported by a grant from the Swedish State Council of Technical Research, which is gratefully acknowledged.

# Effect of Alloying Elements on the Elevated Temperature

## Plastic Properties of Alpha Solid Solutions of Aluminum

by O. D. Sherby, R. A. Anderson, and J. E. Dorn

Solid solution alloying increases the plastic properties of aluminum at elevated temperatures by solid solution strengthening, by restraining recovery and recrystallization, and by a Cottrell effect. When binary aluminum alloys are strained and aged at 194° to 300°K they develop a yield point. This is attributed to a migration of dislocations to solute atoms during aging.

IN view of the ever expanding interest in applications of metals and alloys to high temperature service conditions, it becomes increasingly important to be cognizant of the effect of various metallurgical factors on the strength of alloys at elevated temperatures. One problem of wide interest, not only because of its engineering significance but also due to its fundamental scientific importance, is the elucidation of the effect of alloying elements on the plastic properties of homogeneous  $\alpha$  solid solutions at elevated temperatures. It is indeed astonishing to note that in spite of its importance, and in spite of extensive random testing of alloys at elevated temperatures, no systematic investigation has been reported yet on the effect of alloying additions on the plastic properties of  $\alpha$  solid solutions at elevated temperatures. This deficiency in our knowledge prompted the investigation described in this report.

Rather extensive data are currently available on the effect of alloying elements on the plastic properties of  $\alpha$  solid solutions at atmospheric and sub-atmospheric temperatures. Such data might be ex-

trapolated to higher temperatures and reasonable guesses might be made regarding the influence of such factors as recovery and recrystallization in order to hazard a qualitative estimate of the effect of alloying elements on the plastic properties of  $\alpha$  solid solutions at elevated temperatures. Such

guesses would indicate the recognized factors of importance in the plastic properties of homogeneous alloys at elevated temperatures and would prescribe the interesting variables to be considered in studying the problem more thoroughly. If such guesses prove to be fairly accurate the need for detailed research on the elevated temperature plastic properties will be much reduced.

It is quite possible, however, that other factors, not so widely recognized, may also prove to be important in affecting the elevated temperature plastic properties of alloys. The following investigation was therefore undertaken in order to evaluate more completely the effect of various factors on the solid solution strengthening of alloys at elevated temperatures. Aluminum was selected as the solvent in view of the extensive correlatable data now available on its plastic properties at low temperatures.<sup>1</sup> The general principles uncovered in this investiga-

tion, however, are probably applicable to other systems using higher melting solvents.

### Materials and Method

The compositions and grain sizes of the alloys used in this investigation are given in Table I. Each alloy was homogenized, cold rolled, and then recrystallized to give about the same grain size. The details of these treatments are recorded in a previous publication.<sup>1</sup>

The tensile stress-strain curves for the alloys at elevated temperatures were obtained by means of equipment that has been described in the literature.<sup>1</sup> Strains were determined to a precision of better than  $\pm 0.001$  and the stresses were measured to an accuracy of about  $\pm 25$  psi. All tests, except where otherwise specified, were conducted at an average strain rate of about 0.118 per min.

Elevated temperatures were obtained by placing

Fig. 5—Effect of magnesium on the work hardening of aluminum at 422°K.

Fig. 6—Effect of magnesium on the work hardening of aluminum at 550°K.

Fig. 7—Effect of magnesium on the work hardening of aluminum at 650°K.

a three element electric resistance furnace about the specimen. The upper, central, and lower zones of the furnace were each controlled independently by means of three commercial indicating controllers. A stainless steel liner 2½ in. in diam and 15 in. long was inserted in the center of the furnace in order

to further assure rather uniform temperature over the length of the specimen. Temperatures at three points along the 2-in. gage section of the specimen were measured during the test with iron constantan thermocouples bound to the specimen by means of flexible glass cord. Variations of temperature along

Fig. 9—Effect of test temperature on the flow stress of Al-Mg alloys for a true strain of 0.05.

the length of the specimen were held to less than  $\pm 1^\circ\text{C}$  during any one test.

### Experimental Results

The most pronounced effects of alloying additions on the elevated temperature tensile properties of  $\alpha$  solid solutions in aluminum were exhibited by the Al-Mg series of alloys. The true stress-true strain curves for these alloys over the range from  $78^\circ$  to  $750^\circ\text{K}$  are given in Figs. 1 to 8.

The point at which the maximum load was observed is shown by the solid symbol on each curve. At the lower temperatures of  $78^\circ$  to  $298^\circ\text{K}$ , specimens of all of the alloys began to develop a neck at this point. At the higher temperatures of  $422^\circ\text{K}$  and above, however, necking did not occur when the maximum load was reached. Consequently, the true stress-true strain curves at  $422^\circ\text{K}$  and above were obtainable beyond the point of maximum load.

The stress-strain curves given in Figs. 1 to 8 re-

veal that the effect of alloying additions on the plastic properties of  $\alpha$  solid solutions is dependent on the temperature of testing. At temperatures of about  $298^\circ\text{K}$  and below, magnesium additions result in appreciably higher stress-strain curves than those obtained for the pure aluminum. At the highest test temperature of  $750^\circ\text{K}$ , the alloying additions of magnesium had only a minor effect on the plastic properties of aluminum. The greatest effect of alloying is clearly seen to occur in the intermediate ranges of temperature from about  $298^\circ$  to about  $422^\circ\text{K}$  for the Al-Mg series of alloys. Similar trends also were observed for the remainder of the alloys that were investigated.

The temperature dependence of alloy strengthening upon additions of magnesium to aluminum is revealed more effectively in Fig. 9. In this diagram the flow stress at a fixed strain of  $\epsilon = 0.05$  is plotted as a function of the temperature for each magnesium alloy of the series, including pure aluminum. The strengthening of aluminum due to additions of

Fig. 11—Effect of test temperature on the flow stress of Al-Zn alloys for a true strain of 0.05.

Fig. 10—Effect of test temperature on the flow stress of Al-Cu alloys for a true strain of 0.05.

magnesium is quite substantial over the range from  $78^\circ$  to  $298^\circ\text{K}$ . At  $700^\circ\text{K}$ , however, the strengthening due to magnesium additions is small and becomes negligible at about  $750^\circ\text{K}$ . The maximum effect of alloying additions on the strengthening of aluminum, however, occurs over an intermediate range of temperatures from about  $300^\circ\text{K}$  to about  $425^\circ\text{K}$ .

Similar data for the remainder of the alloys are given in Figs. 10 to 13. Although all of the alloys showed similar trends, the effects were much less pronounced than those of the magnesium series.

### Discussion of Results

The data reported under Experimental Results reveal that the strengthening of aluminum due to alloying additions is dependent on the test temperature. Apparently many factors contribute to this dependency and it will prove interesting to attempt to identify the most important ones.

Consider first the range of temperatures from that of liquid nitrogen ( $78^\circ\text{K}$ ) to that at which recovery first appears to have a significant effect on the tensile stress-strain curve (about  $300^\circ\text{K}$  for

pure aluminum.) In this range of temperatures the plastic properties of alloys are probably ascribable to two factors. The first consists of the increase in the initial flow stress due to alloying. This will be represented by  $\Delta\sigma_s$ , the solid solution strengthening, which is equal to  $(\sigma_{\text{alloy}} - \sigma_{\text{Al}})_{\epsilon=0}$ , the flow stress of the alloy minus that for pure aluminum, where both are measured at the same temperature and at infinitesimally small plastic strains. At greater strains, however, a second factor, namely the difference in strain hardening of the alloy and pure aluminum, enters the analysis. As shown in Figs. 1 to 4, alloying elements not only increase the initial flow stress but they also induce greater rates of strengthening with strain resulting in higher slopes of the stress-strain curves of the alloys than of pure aluminum when the curves are compared at the same temperature and strain. Thus at some given plastic strain larger than zero, the improvement in the plastic flow stress upon alloying  $(\sigma_{\text{alloy}} - \sigma_{\text{Al}})_{\epsilon}$  is due to the increase in the initial flow stress resulting from

Fig. 12—Effect of test temperature on the flow stress of Al-Ge alloys for a true strain of 0.05.

solution strengthening  $\Delta\sigma_s$ , plus the increase in the flow stress of the alloy over and above the increase in the flow stress of pure aluminum upon strain hardening, namely  $\Delta\sigma_e$ .

A preliminary guess based on the hypothesis of dislocations can be made as to how  $\Delta\sigma_s$  varies with temperature. Solid solution strengthening is visualized as arising from the interaction forces between a dislocation and the solute atoms in the alloy. A major part of the interaction force is attributable to the internal stress fields surrounding the dislocation and the solute atoms. It also appears that part of the interaction force might have an electronic origin as revealed by the fact that solid solution hardening is dependent not only on the local lattice strains induced by the solute atoms but also on the difference in valence of the solute and solvent atoms.<sup>1</sup> Cottrell<sup>2,3</sup> has shown that the interaction force arising from the elastic strain energy interaction of a dislocation and a solute atom is proportional to the shear modulus of elasticity according to the relationship:

Fig. 13—Effect of test temperature on the flow stress of Al-Ag alloys for a true strain of 0.05.

$$F = \frac{4}{3} \frac{(1 + \nu)}{(1 - \nu)} \frac{G\epsilon r^3 \lambda}{R^2} \quad [1]$$

where,  $G$  is the shear modulus of elasticity;  $\nu$ , Poisson's ratio;  $r$ , the atomic radius of the solvent;  $\epsilon$  the local lattice strain due to the introduction of the solute atom;  $R$ , the distance between a solute atom and a dislocation; and  $\lambda$ , the strength of the dislocation (shear displacement when a unit dislocation traverses the crystal).

Cottrell's equation is admittedly an approximation to the facts, insofar as it is invalid for values of  $R$  approaching atomic dimensions and also because it is based on the interaction between a single solute atom and a single dislocation, whereas it is widely applied to solid solutions containing many atoms and dislocations. On the other hand, it probably gives a satisfactory qualitative, though distorted, picture of the facts.

In a pure metal  $R$  is infinite and  $F$  is zero. As alloying elements are added, however, the average value of  $R$  between the solute atoms and the dislocations decreases giving significant interaction forces  $F$ . If the alloy and the pure metal contain

Fig. 14—Effect of strain and temperature on the increase in flow stress upon alloying aluminum with 1.618 atomic pct Mg.

Fig. 15—Effect of test temperature on the flow stress of 3.2 pct Mg in aluminum alloy for various strains.

about the same density and distribution of dislocations, the increase in the initial flow stress upon alloying,  $\Delta\sigma_s$ , is primarily ascribable to the increase in  $F$  upon alloying. At higher test temperatures, however,  $F$  decreases because the shear modulus  $G$  decreases with increase in temperature. Consequently,  $\Delta\sigma_s$  should decrease with increasing temperature. This deduction is in part confirmed by the data shown in Fig. 14 for  $(\sigma_{\text{alloy}} - \sigma_{\text{Al}})_\epsilon$  at  $\epsilon = 0.005$ . At such small strains  $\Delta\sigma_s$  is small and, therefore,  $\Delta\sigma_s \approx (\sigma_{\text{alloy}} - \sigma_{\text{Al}})$ . The decrease in  $(\sigma_{\text{alloy}} - \sigma_{\text{Al}})_\epsilon$  for  $\epsilon = 0.005$  with increasing temperatures therefore suggests that  $\Delta\sigma_s$  decreases with increasing temperatures. Confirmation that  $\Delta\sigma_s$  is small at elevated temperatures is shown in Figs. 9 to 13. At the highest test temperatures where the alloys and pure aluminum recover extremely rapidly during the test, the flow strength of the alloys is not significantly greater than that for pure aluminum. These data strongly suggest that  $\alpha$  solid solution alloying is not particularly effective in improving the strength characteristics of a metal for application at temperatures well above the recovery temperature of the alloy. Other methods of strengthening, such as the introduction of intermediate phases, may prove more useful for strengthening in this range of temperatures.

The strain hardening of metals is commonly ascribed to the interaction forces between dislocations. Since alloying additions promote greater rates of strain hardening, it is consistent to assume that this is due to the more rapid accumulation of dislocations in the alloy than in the pure metal. The data of Figs. 1 to 8 reveal that the rate of strain hardening of aluminum and its  $\alpha$  solid solutions decreases with increasing temperatures, suggesting that the rate of accumulation of dislocations is less at the higher temperatures. The data of Fig. 14 show that  $(\sigma_{\text{alloy}} - \sigma_{\text{Al}}) = \Delta\sigma_s + \Delta\sigma_e$  increases for strains above

0.025 with increasing temperatures. Since  $\Delta\sigma_s$  decreases with increasing temperatures,  $\Delta\sigma_e$  must, therefore, increase with increasing temperatures. This suggests that the accumulation of dislocations upon straining decreases less rapidly with increase in temperature in the alloys than in pure aluminum. The detailed explanation of these observations is not yet clear to the authors. The practical significance of the observations, however, is obvious. Alloying additions primarily influence  $\Delta\sigma_s$  at low temperatures, whereas they primarily influence  $\Delta\sigma_e$  at high temperatures within the range where recovery is negligible. In fact, if an extrapolation of the data of Fig. 14 to  $0^\circ\text{K}$  be attempted, it appears as if the curves for various strains will coincide at about 4800 psi, suggesting that alloys of aluminum will strain harden no more rapidly than pure aluminum at the absolute zero temperature. At this temperature the flow stress of 1.62 atomic pct Mg alloy will exceed that for pure aluminum by about 4800 psi for all strains, whereas, at  $300^\circ\text{K}$  and a strain of 0.15, the flow stress for the same alloy will exceed that for pure aluminum by about 11,700 psi. Since the flow stress for aluminum decreases rapidly with an increase in temperature, these differences become yet more pronounced when they are based on a percentage basis.

Previous investigations have shown that pure aluminum begins to exhibit rapid recovery at just about  $300^\circ\text{K}$ . The data shown in Figs. 9 to 13 reveal that the stress-temperature curves of aluminum for a strain of 0.05 drops slightly in this range, indicative that recovery is occurring during the test. Presumably the rapid decrease in the flow stress with increasing temperature shown for the Al-Mg alloys in Fig. 9 at about  $425^\circ\text{K}$  is also indicative of rapid recovery during the test. Further evidence of this contention is revealed by the data recorded in Fig. 15, where it is noted that the temperature at which the flow stress first begins to decrease with increasing temperature is displaced to lower temperatures for the higher strains. Obviously for the strain rate employed in these tests, the 3.2 pct Mg alloy had recovered to the same flow stress for all recorded strains at about  $650^\circ\text{K}$ .

The remainder of the alloys also exhibit the same general trends of a rapid decrease in the flow stress

Fig. 16—Effect of test temperature on the flow stress of various aluminum alloys for a true strain of 0.05.

with increasing temperature in the recovery range of temperatures. The temperature at which the rapid decrease in flow stress first occurs appears to be practically independent of the concentration of the alloying elements in any one series of alloys as revealed in Figs. 9 to 13. On the other hand, as shown in Fig. 16, the temperature at which a rapid decrease in flow stress occurs with increasing temperature is sensitive to the particular alloying element that is present. In this respect the various alloying elements appear to have a unique effect on the plastic properties at elevated temperatures.

The effect of alloying elements on the plastic properties of aluminum alloys is particularly interesting over the intermediate range of temperatures from about 300° to 425°K. In this range the stress-temperature curves exhibit a plateau and, as shown in Fig. 15 for a strain of 0.025, in some instances actually reveal a hump. These data appear to suggest that the alloys are undergoing precipitation hardening over this intermediate range of temperatures in spite of the precautions exercised in selecting the compositions to be below the solubility limit at about 100°C as given by the best data currently available. Errors in extrapolation of the solubility data to atmospheric temperature could have been made, so that the highest composition of each alloy series might have exceeded the solubility limit. But it is quite inconceivable that the lowest compositions, which revealed identical trends, were also supersaturated. Nevertheless tests were made to ascertain whether precipitation had occurred. In view of the possible insensitivity of lattice parameter data and microscopic methods of detection, mechanical tests were considered to be more sensitive indexes of precipitation.

The planned test consisted of prestraining an alloy about 0.05 at 194°K, unloading, and then aging for 5 min at successively higher temperatures, following which the specimen was again to be mechanically tested at 194°K. It was anticipated that if precipitation were responsible for the observed plateaus in the stress-temperature diagrams of the alloys, the stress-strain curve at 194°K, following a prestrain and an aging treatment at some appropriate temperature, would lie above the stress-strain curve for the same alloy when the test had not been interrupted for aging.

The various stress-strain curves that were obtained on the 3.2 pct Mg alloy are recorded in Fig. 17. Curve A reveals that 5 min of aging at 194°K, following a prestrain at 194°K, had practically no effect on the stress-strain curve at 194°K. After aging for 5 min at 250°K, however, a distinct yield point was observed. This yield point became very pronounced following aging at about 295°K. But the yield-point effect was transient since after the yield phenomenon, the stress-strain curve of the aged material again coincided with that for unaged specimens at the same total strain. Thus, it was assumed that no real precipitation had occurred. After aging for 5 min at 371°K, however, the yield-point effect was reduced and the stress-strain curve after yielding fell below that for the unaged alloy, indicating that recovery had occurred during aging at this elevated temperature.

The absence of evidence for real precipitation and the introduction of a yield point upon appropriate aging suggested a strong parallelism between these data and that obtained upon the strain aging of steels.<sup>2,8,5</sup> It was, therefore, considered possible that

during aging the solute atoms might have migrated toward the dislocations under the interaction forces described by Cottrell, solutes larger than the solvent diffusing toward the expanded half of the dislocations and solutes smaller than the solvent diffusing toward the contracted regions of the dislocations. The interaction forces between the dislocations and the atmosphere of solute atoms which concentrated in its environs during aging would then be higher than in the homogeneous  $\alpha$  solid solution. Consequently, a higher than normal stress would be required to cause the dislocations to move after appropriate aging treatments. But once the dislocations have been displaced from their atmospheres, they again move in a more or less homogeneous dispersion of solute atoms and the flow stress again reduces to the usual value obtained for the unaged material at the same total strain.

One major difficulty with the above explanation of the strain-aging phenomenon centers about the small rates of diffusion of the solute atoms at the aging temperature. This will be discussed later. On the other hand, a Cottrell effect of this type could serve to explain the observed plateau in the stress-temperature diagrams even in the absence of precipitation. For example, at low temperatures the solute atoms cannot diffuse sufficiently rapidly to migrate with the dislocations. The increase in the flow stress of the alloy over that for the pure aluminum is then attributable primarily to the solution strengthening,  $\Delta\sigma_s$ , resulting from the interaction forces between the dislocations and the randomly dispersed solute atoms plus the effect of the increased rate of strain hardening  $\Delta\sigma_h$ , that occurs in the alloy. Although the second factor increases with

Fig. 17—Effect of strain-aging treatments on the true stress-true strain curve of 3.2 atomic pct Mg in aluminum alloy at 194°K.

Fig. 18—Effect of strain rate on work hardening of pure aluminum at 295°K.

increasing temperatures, the first factor decreases with increasing temperatures. As higher test temperatures are used, the diffusivity of the solute atoms increases and finally reaches a value which permits their migration with the dislocation under the interaction forces that exist. When this occurs, the flow stress must be sufficiently great to continuously exceed the additional interaction forces between the dislocations and their atmospheres. Consequently, over some range of temperatures, the flow stress will decrease less rapidly than normal, leading to a plateau in the stress-temperature diagram which will be terminated at higher temperatures where rapid recovery occurs. Thus, the increase in the flow stress at high temperatures upon alloying is the increase in the flow stress due not only to the dislocations moving through a solid solution,  $\Delta\sigma_s + \Delta\sigma_e$ , but also to the increase in flow stress  $\Delta\sigma_e$  due to the fact that the solute atoms can migrate with the dislocation.

A critical experimental check on the above-outlined proposal for the cause of the plateau in the stress-temperature diagram is easily obtained. In general, an increase in strain rate causes an increase in the flow stress as shown in Fig. 18 for pure aluminum at 295°K. If the plateau that is obtained in the stress-temperature diagram is ascribable to a Cottrell effect, it follows that over the lower temperature range of the plateau, the atoms have just sufficient diffusivity to migrate with the dislocations. If either the temperature were reduced or the strain rate were increased, the solute atoms could no longer keep up with the moving dislocations. At a low strain rate at this critical temperature, for example, the solute atoms would migrate with the dislocations causing the increase in flow stress due to alloying to be  $\Delta\sigma_s + \Delta\sigma_e + \Delta\sigma_i$ , whereas at the higher strain rates the solute atoms could no longer diffuse with the dislocations, and, consequently, the increase in flow stress due to alloying would be only  $\Delta\sigma_s + \Delta\sigma_e + \Delta\sigma_e^*$ , where  $\Delta\sigma_e^*$  is the increase in the flow stress due to an increase in strain rate. Thus, an increase in strain rate, at some appropriate temperature, might result in a decrease in the flow stress, if  $\Delta\sigma_i$  is greater than the strain rate effect  $\Delta\sigma_e^*$ . Since this is contrary to the usual effect of

strain rate on the flow stress, it serves as a critical evaluation of the hypothesis. As shown in Fig. 19 the 3.2 atomic pct Mg alloy experiences a decrease in flow stress at 295°K with an increase in strain rate as predicted by a Cottrell effect. The large number of overlapping points on the fast strain rate curve are due to the fact that the load increased in a step-like manner for the given constant strain rate employed. Maximum and minimum load readings were observed and plotted in the figure. This occurrence is very similar to the process of deformation observed in aluminum alloys by McReynolds<sup>6</sup> and also Lubahn.<sup>7</sup>

Additional evidence that favors the hypothesis that the observed plateaus in the stress-temperature diagrams of the various aluminum alloys is attributable to a Cottrell effect might be obtained by calculating the density of the edge dislocations per square centimeter of the face of a unit cube of the alloy. If  $\rho$  is the density of the active edge-type dislocations per square centimeter of a unit cube of the alloy, the shear strain rate is:

$$\frac{\dot{\epsilon}}{2} = \lambda v \rho \quad [2]$$

where,  $\dot{\epsilon}$  is the tensile strain rate;  $v$ , the average velocity of the dislocations; and  $\lambda$ , the shear displacement per dislocation.

When the solute atoms diffuse just fast enough to keep up with the moving dislocations, the stream velocity of diffusion is just equal to the velocity  $v$  of the dislocations. It is possible, of course, that a Cottrell effect might also be noted when the velocity of streaming of the atoms is yet slightly below the mean velocity of the moving dislocations. This would give a slightly higher flow stress than in the complete absence of streaming, because many dislocations would carry the solute atoms with them over short distances. Thus, the critical velocity  $v$  of the motion of the dislocations for a Cottrell effect might be slightly larger than the streaming velocity of the solute atoms  $v'$  under the interaction energy between the solute atoms and the dislocations. Cottrell assumed that the streaming velocity  $v'$  is given by the Einstein equation:

Fig. 19—Effect of strain rate on work hardening of 3.2 atomic pct Mg in aluminum alloy at 295°K.

$$v' = \frac{D}{kT} F \quad [3]$$

where,  $D$  is the diffusivity of the solute atoms;  $k$ , Boltzmann's constant;  $T$ , the absolute temperature; and  $F$ , the interaction energy between an atom and a dislocation (eq 1).

If  $v'$  approaches the order of magnitude of  $v$ , a Cottrell effect will be observed, and under these conditions:

$$\rho = \frac{\dot{\epsilon}}{2\lambda v'} = \frac{\dot{\epsilon} kT}{2\lambda D F} \quad [4]$$

The following data might be taken to estimate the value of  $F$  given in eq 1:

$$G = 2.65 \times 10^{11} \text{ dynes per sq cm}$$

$$\nu = 0.33$$

$$r = 1.43 \times 10^{-8} \text{ cm}$$

$$\lambda = 2.86 \times 10^{-8} \text{ cm}$$

$$\epsilon = 0.09$$

$$R = 5 \times 10^{-8} \text{ cm.}$$

The value of  $\epsilon$  was estimated from the change in lattice parameter from 4.0413Å to 4.0449Å upon the addition of 1 atomic pct Mg to aluminum. Then

$$\epsilon = \frac{100 \Delta a}{a} = \frac{0.0036 \times 100}{4.04} = 0.09. \text{ The value of } R$$

was estimated by assuming a random distribution of the magnesium atoms in the 3.2 atomic pct Mg alloy. Since there are 4 atoms per unit cell in aluminum the volume surrounding a magnesium atom would be  $\left(\frac{100}{p}\right) \frac{a^3}{4}$  where  $p$  is the atomic percentage of magnesium. The mean distance,  $R$ , between any dislocation and an atom is then given by:

$$4/3 \pi R^3 = \frac{100}{p} \frac{a^3}{4}$$

Introduction of 3.2 for  $p$  and  $4.04 \times 10^{-8}$  cm for  $a$  gives  $R = 5.0 \times 10^{-8}$  cm. Of course, the data reveal that the initiation of the plateau in the stress-temperature diagrams occurs at approximately the same temperature for all compositions, suggesting that this estimate is not critical. Introducing these values into eq 1 reveals that  $F \cong 10^{-6}$  dynes.

In order to estimate  $\rho$  from eq 4 the following data were assumed:

$$\dot{\epsilon} = \text{between } 0.4 \times 10^{-6} \text{ to } 190 \times 10^{-6} \text{ per sec} \\ (\text{from Fig. 19})$$

$$T = 295^\circ \text{K}$$

$$k = 1.38 \times 10^{-16} \text{ dyne-cm per degree}$$

$$\lambda = 2.86 \times 10^{-8} \text{ cm}$$

$$F \cong 10^{-6} \text{ dynes}$$

$$D = 5 \times 10^{-28} \text{ to } 5 \times 10^{-28} \text{ sq cm per sec.}$$

The values of  $D$  for magnesium were obtained by extrapolating from ordinary diffusivity data at elevated temperatures to atmospheric temperature. The wide range of values quoted above for  $D$  results from differences in the activation energies of magnesium in aluminum reported by various investigators.<sup>8-10</sup> It is conceivable that the correct value of  $D$  to be applied to the cold-worked Al-Mg alloy is several orders of magnitude greater than the extrapolated values. When the above values are introduced into eq 4 the values of  $\rho$  range from  $\rho_{\min} = 5 \times 10^{15}$  per sq cm to  $\rho_{\max} = 3 \times 10^{28}$  per sq cm. Obviously  $\rho_{\max}$  is much too large. On the other hand,  $\rho_{\min}$  begins to approach the value of  $\rho$  of  $10^{12}$  quoted

Fig. 20—Effect of a strain-aging treatment on the true stress-true strain curve of 3.2 atomic pct Mg in aluminum alloy at 194°K.

by Seitz and Read<sup>11</sup> for severely cold-worked metal. If the actual diffusivities in the cold-worked metal could be about 5000 times those for the annealed state,  $\rho_{\min}$  would reduce to about  $10^{12}$  in fair agreement with the estimate made by Seitz and Read. It appears, however, that several improvements in analysis and data will have to be made before quantitative agreement between theory and experiment can be achieved in this field.

Although the decrease in flow stress resulting from an increase in strain rate is probably ascribable to the fact that the solute atoms cannot diffuse sufficiently rapidly to migrate with the dislocations, it is by no means certain that the yield-point phenomenon upon aging is also attributable to the diffusion of the solute atoms to the dislocations. It is quite possible that the dislocations might migrate with greater ease toward the solute atoms during aging than the solute atoms can migrate toward the dislocations. If the solute atoms were diffusing toward the dislocations, the activation energy for the yield-point phenomenon would be that for the diffusion of the atoms, but if the dislocations were more mobile than the solute atoms the activation energy for the strain-aging process should be that for the activation of dislocations. Inasmuch as dislocations are activated during recovery at 298°K in pure aluminum, whereas the rate of migration of solute atoms is quite low at this temperature, preference must be expressed for the process involving the migration of dislocations to account for the observed yield-point phenomenon. This preference is emphasized by the data shown in Fig. 20. Careful prestraining at 194°K at a slow strain rate of  $\dot{\epsilon} = 0.0064$  per min, unloading, aging at 194°K for 420 min, and then continuing the straining at 194°K gives a well-defined yield point. At this temperature the diffusivity of magnesium in aluminum is about  $10^{-30}$  sq cm per sec, strongly suggesting that the yield point induced by strain aging cannot be ascribed to the migration of the solute atoms. The values of the yield-point hump  $\Delta\sigma$ , which is defined in Fig. 20,

Fig. 21—Effect of strain-aging treatments at various times and temperatures on the increase in flow stress  $\Delta\sigma$ . 3.2 atomic pct Mg in aluminum alloy.

were obtained at 194°K after aging for various times and temperatures as shown in Fig. 21. Calculations based on these data suggest that the activation energy for the aging process is indeed low. No single activation energy, however, could be found. For small values of  $\Delta\sigma$  a low average activation energy of about 8000 cal per mol was obtained. The average activation energies for higher values of  $\Delta\sigma$  were estimated to be about 10,000 cal per mol, and yet higher values of  $\Delta\sigma$  suggested average activation energies of about 15,000 cal per mol. Since these values of the activation energy are less than half of the accepted values of activation energy for diffusion of magnesium in aluminum, the aging process cannot be attributed to diffusion of magnesium. These trends of increasing activation energies for increasing values of  $\Delta\sigma$  are highly reminiscent of the variation in activation energies for recovery which were previously reported.<sup>12,18</sup> It appears as if the smaller loops of the dislocations which have lower activation energies migrate rapidly and subsequently the more difficultly activated dislocation loops are induced to migrate to the solute atoms. Thus, the mean activation energy for the process steadily increases as the process proceeds.

### Conclusions

- 1—The effect of various alloying elements on the plastic properties of  $\alpha$  solid solutions of aluminum at elevated temperatures was studied.
- 2—The solid solution strengthening of the annealed metals decreases with increasing temperature as predicted by the dislocation theory.
- 3—On the other hand, the alloys exhibited greater relative rates of strain hardening than aluminum as the test temperature was increased.
- 4—Solid solution alloying is not very effective in improving the flow strength of aluminum at high temperatures where both the pure aluminum and the alloy recover rapidly.
- 5—In an intermediate range of temperatures from 300° to 425°K, the alloys showed the most pronounced improvement in flow stress over that for pure aluminum.
- 6—Some of this improvement was attributed to

the restraint offered by the alloying elements to recovery.

7—The major factor causing solid solution hardening in the intermediate range of temperatures, however, was shown to arise from the migration of the solute atoms with the dislocations as postulated by Cottrell.

8—When aluminum alloys are aged after straining, they develop a yield point. This occurs even when the straining and aging is done at 194°K and is probably attributable to the migration of dislocations to the solute atoms.

### Acknowledgments

This investigation is part of a more extensive program of research on the effect of alloying elements on the plastic properties of aluminum alloys sponsored by the Office of Naval Research. The authors wish to express their appreciation to the O.N.R. for its continued interest throughout the course of these studies. They are especially grateful to the Aluminum Research Laboratories and their staff for furnishing the alloys that were investigated and their chemical analyses.

In addition, the authors wish to thank T. E. Tietz and C. D. Starr for their helpful criticisms and numerous suggestions made during the conduct of this study. To Mrs. G. Pelatowski they extend their sincere appreciation for her careful preparation of the many figures in this report.

# Structural Studies of Plastic Deformation

## In Aluminum Single Crystals

by N. K. Chen and C. H. Mathewson

Single crystals of high purity aluminum of various orientations were carefully documented after plastic extension. Special attention was given to the formation of slip lines, deformation bands, and asterism. An explanation for the geometry and mechanism of formation of deformation bands is considered.

WHILE the general process of plastic extension of face-centered cubic metals is well understood,<sup>1</sup> the accompanying structural changes due to slip and rotation are far more complex than ordinarily assumed.<sup>2-5</sup> In the case of stretched single crystals of aluminum, the complicated behavior is especially marked by the formation of deformation bands, as first indicated by Collins and Mathewson.<sup>3</sup> Such bands were believed by them and also by others,<sup>6, 7</sup> who have discussed banded structure in general, to represent one of the important modes of lattice reorientation and to be intimately connected with the recrystallization process. Yet, despite their fundamental importance to the understanding of the mechanism of both plastic deformation and recrystallization, practically no study of the crystallographic features of these bands in their relationship to the conventional slip process has been attempted.

This paper describes part of an extensive investigation on the structural behavior during plastic deformation of aluminum single crystals and is especially concerned with the characteristics of deformation bands. The investigation of the subsequent recrystallization of deformed aluminum single crystals will be discussed in a later publication.

### Experimental Procedure

Single crystal specimens of 99.996+ pct pure aluminum, 1/2 in. in diam and 5 to 6 in. in length were made both by the Bridgman method<sup>8</sup> and by a modified temperature gradient method.<sup>9\*</sup>

Discussion on this paper, TP 3100E, may be sent, 2 copies, to AIME by Dec. 1, 1951. Manuscript, March 6, 1951. Detroit Meeting, October 1951.

This paper represents part of a thesis by N. K. Chen submitted in partial fulfillment of requirements for the degree of Doctor of Engineering to the Graduate School of Engineering, Yale University.

Crystals were selected in which the lineage deviation did not exceed 2°; i.e., as determined from the back-reflection Laue X-ray photograms. These crystals were radiographed to insure that no internal porosity was present. The orientations showed good coverage of the whole area of the Taylor and Elam triangle.<sup>1</sup> Orientations of the crystals were obtained by the back-reflection Laue technique described by Greninger.<sup>10</sup>

Crystals so selected were tapered very carefully in a lathe to obtain a linear decrease in diameter from 0.500 to 0.350 in. along a gage length of 3 in. This is considered desirable because it permits a strain gradient to be introduced in a single specimen at one initial orientation. The advantages of tapered crystals for studying the development of slip lines and recrystallized grains have been pointed out by previous investigators.<sup>11</sup> The cold-worked layer resulting from the machining operation was removed by alternate etching in aqua regia and careful polishing with 2/0 emery paper until undistorted Laue back-reflection spots were obtained. A homogenization treatment at 600°C for 24 hr was then introduced to insure the removal of residual stress. Two of the crystals so prepared were also checked by use of a glancing angle technique. Using a copper target, at 30 kv and 10 microamperes, a monochromatic beam was positioned at right angles to the axis of the crystal about which it rotated. The time of exposure was 24 hr. From these X-ray photograms, it was concluded that the present method of preparation of single crystals is satisfactory.

Following this procedure, the crystals were electrolytically polished in a 2:1 solution of methyl alcohol and concentrated nitric acid. Intermittent

\* A third method, a particular type of strain-anneal technique, developed in the present investigation, was also used for specimen preparation. It differs in a striking way from the ordinary strain-anneal procedure in that a tapered single crystal of one orientation can be transformed to another single crystal of a different orientation by first stretching it (not a critical amount) and then annealing it isothermally at a high temperature. The details will be discussed in a separate publication.

polishing periods of from 10 to 12 min at a current density of 10 amp per sq dm resulted in a high polish and smooth metallographic surface. Fine black lines then were painted on each specimen at  $\frac{1}{4}$ -in. intervals. These intervals were carefully measured in a Zeiss metallograph at a magnification of X77, yielding an accuracy of  $\pm 0.05$  mm.

The straining of the specimens was carried out for the most part on a Southwark Emery 20,000-lb hydraulic testing machine equipped with self-aligning grips and gimbals. The rate of loading was approximately 100 lb per min, and the load values could be estimated to 5 lb. In two cases (first extension of crystals A-2 and A-4) the loading equipment devised by Miller<sup>12</sup> and modified by Rosi<sup>13</sup> was used. In their equipment, uniform flow of sand produced loading at approximately 3 lb per min. The average of repeated measurements of the gage intervals painted on each crystal before and after extension gave a mean value of elongation for each gage section after extension as measured by an optical micrometer. A series of back-reflection Laue photograms per gage interval gave reorientation values in terms of  $\lambda$  and  $\chi$ , where  $\lambda$  is the angle between the specimen axis and the primary slip direction and  $\chi$  is the angle between the specimen axis and the primary slip plane. These values were used to calculate the elongation, resolved shear stress and shear, according to classical crystal mechanics.

The gross orientation changes of each tapered crystal are plotted in Fig. 1. During extension the stress axes of the crystal rotated, generally, toward the slip direction in the usual manner. In some cases when a symmetry position was reached, the lattice rotation did not obey the classical behavior; i.e., towards an equilibrium position at  $\langle 112 \rangle$ . In these cases, the stress axes continued to rotate toward the slip direction. This behavior has been generally observed in cylindrical and tapered  $\alpha$  brass single crystals.<sup>11, 14</sup> It should be noted, however, that both the measured and the observed values of reorientation of any tapered section of the crystal constituted an average representation of the lattice changes during deformation. It became clear that after asterism had

developed, orientation determined by X-rays actually should be plotted as a range of orientation rather than a single axial position. The stress-strain curves indicated differences in the strain-hardening characteristics of the different specimens, but the nature and cause of these variations has not been established.

### Slip Lines and Deformation Bands

In all crystals, primary slip lines occurred in close association with cross-slip lines during the early stages of deformation. Early slip on the conjugate plane<sup>15</sup> was observed in crystals of certain orientations such as, A-7, A-5, A-16, and A-18. These lines were irregularly spaced (Fig. 2a) and, generally, discontinuous over primary slip clusters (Fig. 2b). It is clearly seen from Fig. 2b that the conjugate slip segments are displaced by primary slip lines formed subsequent to this slip on the conjugate plane.

Generally it is assumed that the slip bands in aluminum single crystals are quite regularly spaced. Nevertheless, in the present investigation, an orientational effect was found to exist. All crystals having their stress axes located near  $\langle 111 \rangle$  showed slip clusters during extension (Fig. 3a and b), whereas crystals oriented well away from  $\langle 111 \rangle$  exhibited dispersed slip lines (Fig. 3c, d, and e), or barely developed clusters; which were also observed in crystal A-18 having its axis near  $\langle 100 \rangle$  (see Fig. 2a). Since deformation bands were not found in crystals con-

taining slip clusters, a close correlation seems to exist between the orientations concerned in the slip process and the generation of deformation bands. Furthermore, a similarity exists with brass crystals which always exhibit clustered slip lines, but no deformation bands as far as we can learn.

On an electrolytically polished surface, the deformation bands in an early stage of formation (shear about 0.05) can best be described as striations which reflect under very low magnifications or even to the naked eye. They would seem to disappear on observation under high magnification, as the observed slip lines give no indication of a banded arrangement. Thus, there is the likelihood of overlooking them in ordinary metallographic examination.

Deformation bands could be revealed by etching as shown in Fig. 4, with properly controlled conditions. A modified aqua regia solution (three parts HCl, one part HNO<sub>3</sub>, one part H<sub>2</sub>O) as an etchant after the crystal was polished with 2/0 emery paper was found to give very satisfactory and reproducible results. At the early stages of deformation (shear about 0.04 to 0.08), the boundaries of the bands could be easily identified as plane surfaces with elliptical peripheries on the cylindrical specimen. The distance between any two bands was not quite uniform, for at the large end of the tapered crystal they were more widely spaced than at the small end. Nevertheless, in the early stages of deformation, the average distance between bands was of the order of 1 mm.

Fig. 4—Deformation bands in crystal A-1'.

Shear is 0.11 to 0.08. Average distance between bands appearing on the surface is 1.2 mm. Etched in modified aqua regia solution. X4.

As the deformation increased, the bands also increased in intensity (but not in width) and became wavy. New bands of lesser intensity and more imperfect development were also generated between the older ones as shown in Fig. 5 representing crystal A-2. These pictures confirm the observation previously made by Collins and Mathewson<sup>3</sup> that the "... bands varied in thickness and character. When viewed from one point, they appeared straight and regular while from another, they appeared forked and wavy. When held in a certain position they reflected light strongly, as a twin would, while the remaining part of the crystal was dark."

On the unetched surface, the bands, after considerable extension seemed to show ridges and valleys as may be seen in Fig. 6a and b. With one of the crystals in which the strained surface was first etched and later repolished electrolytically, the bands appearing after the second extension could be resolved in some locations, indicating their narrow width, as shown in Figs. 7 and 8a. This width is about 0.038 mm and the average spacing about 0.3 mm. The slip lines crossing the band change their direction as would be the case if the material in the band lagged behind the material in the matrix during the process of lattice reorientation. This was found to be true by subsequent X-ray examination. In other cases revealing slip lines across a band of no clearly resolvable width, Fig. 8b, the directional changes of the slip lines were in agreement with the above statement.

#### Crystallographic Location of Deformation Bands

Two methods were used in determining the crystallographic location of deformation bands at the early stages of formation (shear below 0.10). One method consisted of measuring the azimuth angle of the band (the horizontal angle around the circumference of the crystal from the reference mark to the element containing the minimum or maximum point of the band) and the angle which the band made with the stress axis. The crystal was centered end for end on a one-circle goniometer, with the reference mark coinciding with the vertical cross-hair of a comparator which was also vertically located for the purpose of measuring the vertical difference from an arbitrary horizontal plane at various locations around the conical surface. With the diameter of the crystal corresponding to the maximum and minimum point of the band known, the required results could be obtained either graphically or by calculation. The other method was to determine the trace of the band on two known reference planes under the micro-

scope. In all the cases the pole of the band was found to coincide with the slip direction within experimental error.

The resulting data are summarized in the stereographic plot, Fig. 9. It is seen that more than half of the crystals have produced bands but that an area of orientation spreading out from the octahedral pole is exempt from band formation. These crystals, without band formation, were characterized by irregularly spaced slip lines of a strongly clustered appearance. In the subsequent recrystallization studies, it was found that in the absence of band formation, the inner face of crystal growth lies parallel to the old glide plane, whereas with band formation, the growing face is decisively affected by the band.

#### Mechanism of Band Formation—X-ray Results

The fundamental process which causes the formation of deformation bands is believed to be due to the necessity for inhomogeneous rotations (within and adjacent to a band) in a forced pattern of flexural

gliding wherein the slip direction conventionally approaches the axis. This recalls the action of bend planes in zinc crystals, as described in 1934 by Miller.<sup>16</sup> However, in the present case, there are paired bend planes defining an intermediate band in which the process of reorientation is restrained,

Fig. 7—Slip lines crossing deformation bands in crystal A-1'. Deformation bands were first generated after a shear of 0.05 corresponding to a reorientation of about 1°. Repolished electrolytically and again extended to a shear of about 0.20 corresponding to a reorientation of 8°. Taken at a position perpendicular to the plane containing the reference mark along the crystal and the stress axis. The stress is horizontal. X118.

or held to a minimum. This corresponds to that part of the Miller crystal which is prevented from slip and reorientation by an anchorage to polycrystalline material intentionally introduced for this purpose. X-ray studies of the bands in the very early stages of deformation (shear below 0.1) have indicated that both the axis of rotation and the sense of rotation corresponding to extension of the crystal could be properly correlated with the formation, structure, and location of the bands. An analysis of the situation follows:

As a rule, it was found that in the very earliest stage of deformation, when the bands are far apart (approximately 1 mm), the X-ray photograph taken on a band would give clear indication of distortion with a range of orientation of about  $2^\circ$ , whereas a photograph from the region between the two bands would show little or no asterism. This can be illustrated in Fig. 10a and b. In this case the width of the band was believed to be of the order of a few hundredths of a millimeter, and the spacing between bands along the crystal surface was about 1.7 mm. The X-ray beam was collimated by means of a pin-hole 0.5 mm in diam  $\times$  2.5 in. long. Therefore, when the X-ray beam was carefully adjusted to the band, it also covered some material outside of the band (Fig. 10a). But it impinged only on the slipped matrix when adjusted to the material between bands. After stereographically plotting the streaks seen in Fig. 10a, an axis of rotation could be located as clearly indicated in Fig. 11. This is the  $\langle 112 \rangle$  direction in the slip plane, normal to the slip direction. This axis of rotation could also be derived from plot of other X-ray photographs taken on the same band but with the beam located at a point around the conical surface  $90^\circ$  from the first position. It should be noted here that this axis of rotation is also the line of intersection of the primary slip plane and the plane of the deformation band.

In order to study the sense of the rotation, Fig. 10a and b and the film representing the original orientation of the crystal before extension were carefully superimposed. It was found, as indicated in Fig. 11, that the orientation of the slipped matrix corresponds to the left-hand part of each elongated streak, whereas the original orientation before ex-

Fig. 10—Back-reflection Laue photographs taken on crystal A-12' after the first extension. Shear 0.08. X-ray beam was carefully located: a (left) on a deformation band, and b (right) between deformation bands immediately adjacent to position a.

tension coincides with the right-hand edge of the streak. This implies that while maxima in the Laue streaks represent the slipped matrix, the continuous background arises from the structure of the deformation bands. Examination of this situation shows that the sense of rotation about  $\langle 112 \rangle$  is counter-clockwise, which is in agreement with the rotational requirements of a slip process in which the slip direction, IV, approaches the stress axis, T, during extension. It should be noted, therefore, that the material in the band has lagged about  $2^\circ$  behind the matrix in this process of lattice reorientation. A standard projection summarizing these facts is shown in Fig. 12.

Similar analyses were carried out for rotations associated with deformation bands in other crystals. In all cases examined, excellent agreement with the above conclusions was obtained.

In crystals without band formation, no measurable amount of asterism could be noted in the Laue spots up to a shear of about 0.15. In such cases, X-ray photographs taken on and between areas with clustered slip bands represent the same orientation. This, again, brings out the similarity to brass crystals in which asterism is absent up to a shear of about 0.46.<sup>15</sup>

### Micrographic Analysis

The microstructure shown in Figs. 7 and 8a give good visual information concerning the formation and rotation of the bands. A stereographic projection referring to this particular region, representing the orientation changes of crystal A-1' after the second extension, is shown in Fig. 13. The axis of

Fig. 11—Stereographic representation of the asterism of Fig. 10a.

rotation after the first extension; i. e., when the band was formed, was not measurable by means of X-rays (calculated shear, below 0.05), but the amount of axis rotation for the second extension was found to be  $8^\circ$ . Since the projection plane here coincides with the plane of observation, traces on the micrographs can easily be compared with the orientation plot. Thus, Fig. 14a and b were drawn from these indications. It is seen that the prediction embodied in Fig. 14b is in good agreement with the angular measurements actually made on the crystal, Fig. 14a, except that the axis of the band is not strictly parallel to *S-S* or *Q-Q*, following the analysis of Fig. 13, but lies in the direction *R-R* making a somewhat smaller angle with the stress axis. This probably indicates that the band was actually formed along the line *S-S*, as would be determined after the first extension, and has rotated toward the stress axis, but in the opposite direction to the rotation of the slip planes.

### Rotation of Deformation Bands

The question arises as to whether, after initial formation of a band, the two "bend planes" would move away from the stress axis during further rotation of the slip planes or would move toward the stress axis, but in the opposite direction to the rotation of the slip planes. Experiments seem to furnish many illustrations confirming this latter condition. It was more difficult to obtain clear evidence of the former condition, but it is believed that this also may have occurred.

For example, deformation bands developed in the first extension of crystal A-12' were carefully traced with a sharp pencil. The crystal was then subjected to a second extension causing both the bands and the markings to rotate. The bands, behaving quite similarly to the mechanical marks, rotated toward the stress axis as the crystal elongated. The coincidence of the marks and the boundaries was not quite perfect because the bands became wavy during the large amount of rotation. New bands formed between the earlier bands, with an even more wavy and irregular appearance, and a larger inclined angle to the stress axis than in the case of the initial bands. This implies that these new bands may have formed as a result of flexural gliding of the slip planes at their progressively reoriented positions.

Another example of the rotations of the bands themselves was encountered in the second extension of crystal A-2 plotted stereographically in Fig. 16 (cf. also Fig. 5). In the subsequent recrystallization process, new grains formed in this crystal along the boundaries of the initial bands but in their rotated positions.

No detailed study has been attempted with respect to the crystallite rotations within a narrow band.

Fig. 15—Irrregular deformation bands in crystal A-18.

X150.

which must accompany the progressive rotations of the matrix during deformation. X-ray photographs have indicated, however, that the range of orientation increased as deformation proceeded, confirming this type of rotation. The number of intensity maxima also increased. This may be due to the development of new bands.

## Discussion of Results

Deformation bands produced in the extension of aluminum single crystals possess, in general, the same characteristics as the banded structures found in other metals, after different types of deformation,<sup>6,7</sup> such as a gradual development of orientation differences between bands and matrix, and an unchanging width of the bands during progressive deformation. However, in the early stages of band formation, there is clear evidence of a process of crystal slip and abrupt flexural gliding at band boundaries, similar to the action of the "bend plane" which Miller observed in zinc.<sup>16</sup> A "bend plane" is the locus of the axes around which the slip planes

bend in this modification of simple flexural gliding. Thus, a pair of bend planes defines a band in which the reorientation lags behind that of the matrix material in the process of axial extension. A diagrammatic illustration is given in Fig. 17, embracing the following experimental facts:

- 1—The slip direction constitutes the pole of the band.
- 2—The reoriented material in the band lags behind that of the slipped matrix about  $2^\circ$  at an early stage of observation.
- 3—The axis of rotation in the process of band formation is  $\langle 112 \rangle$  which is also the intersection of the slip plane with the parallel planar boundaries of the band.
- 4—The slip lines change directions in crossing a band.

Recent studies by Hess and Barrett on the kink bands in zinc<sup>7</sup> also revealed an axis of rotation of the same general character. Thus, it would be profitable to examine other metals with respect to band formation and the details of reorientation during plastic deformation.

The tendency towards formation of deformation bands is orientationally dependent in the present case of axial extension of aluminum single crystals. Generally it has been assumed<sup>9</sup> that this tendency depends upon the orientation of the crystal or grain with respect to the direction of flow. Thus an iron

crystal having a  $\langle 100 \rangle$  or  $\langle 111 \rangle$  axis parallel to the axis of compression will form no bands, but crystal of all other orientations become banded.<sup>6</sup>

Homogeneous rotation of the lattice during extension is prohibited because of constraints imposed by grips and by unslipped matrix material. The methods hitherto assumed by which a lattice could rotate and still satisfy the boundary conditions in aluminum have been flexural gliding<sup>17</sup> and crystal fragmentation.<sup>18</sup> The presence of asterism in the Laue X-ray photograms has been interpreted by various investigators as evidence in support of both mechanisms. In brass, collateral slip on cross and conjugate slip planes is assumed to contribute to lattice reorientation and thus modifies the pattern of asterism.<sup>4, 15</sup> It is shown here, however, that asterism in extended aluminum single crystals may arise entirely from the presence of deformation bands. In crystals which do not produce bands, no asterism was found up to a shear of 0.15, similar to the earlier observations on brass. Thus, it is believed that the absence of asterism in aluminum crystals indicates a modified condition of inhomogeneity due to cross-slip and early conjugate slip. Similar correlations between asterism and deformation bands in stretched aluminum crystals have recently been obtained by Cahn and Honeycombe.<sup>19, 20</sup>

There is a further similarity between aluminum single crystals oriented near  $\langle 111 \rangle$  and brass in that slip bands are much more irregularly spaced in such orientations, assuming a strongly clustered appearance. Thus the density of slip bands in such orientations should be expected to be much less than for crystals of other orientations. Actual measurement of slip bands in aluminum in the early stages of extension confirms this general orientational relationship.<sup>21</sup>

Strain hardening characteristics could not be correlated with differences in the appearance of slip lines. Since deformation bands were not found after extension in crystals of aluminum containing slip clusters nor in brass, it seems that dispersed slip lines indicate the probable generation of deformation bands. According to the mechanism previously described a band must traverse a slipped matrix throughout its entire course, and it is clear that prominent slip clusters are not conducive to band formation in the present sense.

### Conclusions

1—The tendency towards the formation of deformation bands in the plastic extension of aluminum single crystals is orientationally dependent. Axes oriented near  $\langle 111 \rangle$  in the standard projection do not lead to band formation.

2—The slip direction constitutes the pole of the band and the axis around which the slip direction changes its orientation is the intersection of the glide ellipse with the band ellipse, namely  $\langle 112 \rangle$ .

3—A mechanism is considered whereby a pair of bend planes defines a band in which the reorientation lags behind that of the matrix material in the process of axial extension.

4—Asterism found in the early stages of extension of aluminum is due to deformation bands, while the absence of asterism in crystals with no band formation in an early stage of deformation indicates that the inhomogeneities of deformation have been modified by cross-slip and early conjugate slip.

5—Crystals which develop bands reveal more regularly dispersed slip lines than crystals which do not

produce bands. In the latter case, a distinct clustering of the slip lines is invariably observed. This correlates properly with the plastic behavior of brass crystals, which develop slip clusters, but no deformation bands.

6—The band structure here observed possesses certain general features previously observed in deformation bands. A rotation of the bands after their initial stage of formation is confirmed and various possibilities in this direction are critically examined.

### Acknowledgments

The authors wish to extend their gratitude to W. R. Hibbard, Jr., of the Yale Metallurgical faculty, for his constructive criticism throughout the course of this investigation and to M. L. Kronberg and R. Maddin for their helpful discussions. Thanks are also due to the Aluminum Company of America for supplying the high purity aluminum used.

# Theory of Grain Boundary Migration Rates

by David Turnbull

IN isothermal recrystallization processes, new crystals generally grow into the matrix until they impinge upon other new crystals or an external surface, at constant linear rates  $G$ . Before impingement the perceptible course of growth can be described by the equation:

$$l = G(t - \tau) \quad [1]$$

where,

$$G = dl/dt,$$

$l$  is a crystal dimension measured in a constant direction,  $t$  is the time, and  $\tau$ , the nucleation period, is a positive intercept on the time axis. Fig. 1 is a schematic representation of  $l$  as a function of time for a recrystallizing grain.  $G$  is dependent upon temperature, driving energy (strain or surface energy), relative grain and boundary orientations, but is generally independent of time. The frequency of nucleation,  $\dot{N}$ , (time<sup>-1</sup> volume<sup>-1</sup>) can be defined by the equation:

$$\dot{N} = 1/\bar{\tau}V \quad [2]$$

where  $\bar{\tau}$  is the mean nucleation period and  $V$  is the volume of the specimen that has not recrystallized. The kinetics of primary and secondary recrystallization generally can be described satisfactorily in terms of the parameters  $\dot{N}$  and  $G$  only.<sup>1-3</sup>

After recrystallization is complete the average grain size  $\bar{l}$  increases with time by "normal grain growth;"  $d\bar{l}/dt$ , the average rate of grain growth, is strongly time dependent and has not yet been precisely related to  $G$  for the motion of the individual grain boundaries constituting the system.

It has been suggested<sup>4, 5</sup> that the elementary act in grain boundary migration is closely related to the elementary act in grain boundary self-diffusion. Although the distance of atom movement in the two processes may be somewhat different, there is reason to expect that the activated states may be very similar, so that the free energy of activation for grain boundary migration should be of the same order of magnitude as for grain boundary self-diffusion. Therefore, it is desirable to develop a satisfactory basis for comparing data on self-diffusion and grain boundary migration and to make such comparisons where possible.

## Theory

The formal theory of grain boundary migration rates is analogous to the theory for the rate of growth of crystals into supercooled liquids reviewed elsewhere.<sup>6-8</sup> Borelius<sup>9</sup> has shown that the latter theory describes, within the theoretical uncertainty, the growth of selenium crystals into supercooled liquid selenium. Mott<sup>9</sup> and more recently Smoluchowski<sup>10</sup> have derived expressions for the rate of

boundary migration in recrystallization. The treatment to be presented is similar to Mott's excepting that the formalism of the absolute reaction rate theory will be used.

The atomic mobility,  $M$ , in grain boundary migration is defined by:

$$G = -M\delta\mu/\delta x \quad [3]$$

where  $\mu$  is the chemical potential per atom and  $x$  is the coordinate measured in the direction of grain boundary movement. Let  $\Delta F$  be the free energy difference per gram atom on the two sides of the boundary and  $\lambda$  the thickness of the boundary. For  $RT \gg \Delta F$  the potential gradient across the boundary ( $\delta\mu/\delta x$ ) is essentially linear and it follows that:

$$\delta\mu/\delta x = -\Delta F/N\lambda \quad [4]$$

where  $N$  is Avogadro's number. According to the Nernst-Einstein equation,  $M$  is related to a diffusion coefficient,  $D_g$ , for matter transport in grain boundary migration by the equation:

$$M = D_g/kT \quad [5]$$

Substituting eqs 4 and 5 into eq 3 gives the basic relation between  $D_g$  and  $G$ :

$$G = D_g\Delta F/\lambda RT \quad [6]$$

$D_g$  values may be calculated from experimental values of  $G$  from eq 6 and directly compared with the coefficient of self-diffusion within the crystal,  $D_L$ , or the grain boundary self-diffusion coefficient  $D_B$ . However, a more convenient, though equivalent, basis for comparing atomic mobility in grain boundary migration and self-diffusion is through the constants of the absolute reaction rate theory. According to this theory diffusion coefficients may be written:<sup>11</sup>

$$D = \lambda^2(kT/h) \exp [-\Delta F_A/RT] \quad [7]$$

$\Delta F_A$ , the free energy of activation, is related to the measured energy of activation,  $Q$ , by the equation:

$$\Delta F_A = Q - T \Delta S_A - RT \quad [8]$$

where  $\Delta S_A$  is the entropy of activation. Substituting eqs 8 and 7 into eq 6 gives:

$$G = e \lambda (kT/h) (\Delta F/RT) \exp [(\Delta S_A)_g/R] \exp [-Q_g/RT] \quad [9]$$

where the subscript  $G$  refers to boundary migration. The relationship between the driving free energy and the free energy of activation in boundary migration is indicated schematically in Fig. 2.

Experience indicates that the variation of  $G$  with temperature can be described by:

$$G = G_0 \exp [-Q_g/RT] \quad [10]$$

where  $G_0$  and  $Q_g$  are generally temperature independent over wide ranges of temperature. Comparison of eq 9 with eq 10 gives:

$$G_0 = e \lambda (kT/h) (\Delta F/RT) \exp [(\Delta S_A)_g/R] \quad [11]$$

D. TURNBULL, Associate Member AIME, is Research Associate, Research Laboratory, General Electric Co., Schenectady.

Discussion on this paper, TP 3103E, may be sent, 2 copies, to AIME by Dec. 1, 1951. Manuscript, March 1, 1951. Detroit Meeting, October 1951.

Fig. 1—Size of a growing grain as a function of time in primary or secondary recrystallization processes.

Fig. 2—Representation of free energy relationships between atoms on lattice sites A and B on opposite sides of a grain boundary.

Also it is found experimentally that:

$$D = D_0 \exp [-Q/RT] \quad [12]$$

By comparing eqs 7 and 12:

$$D_0 = e \lambda^2 (kT/h) \exp [\Delta S_A/R] \quad [13]$$

The relation between atomic mobility and free energy of activation is from eqs 5 and 7:

$$M = \lambda^2 (1/h) \exp [-\Delta F_A/RT] \quad [14]$$

From eq 14 it follows that the ratio of the atomic mobility in grain boundary migration to that in self-diffusion is, to within an order of magnitude, the same as the ratio of the corresponding factors  $\exp [-\Delta F_A/RT]$ .

#### Comparison of Free Energies of Activation for Self-Diffusion and Grain Boundary Migration

**Primary Recrystallization:** The free energy and entropy of activation in self-diffusion processes were calculated from the experimentally determined constants  $D_0$ ,  $Q_L$ , and  $Q_B$  (where  $L$  refers to lattice

self-diffusion and  $B$  to grain boundary self-diffusion) using eqs 13 and 8. However, in order to calculate the free energy  $(\Delta F_A)_G$  and entropy  $(\Delta S_A)_G$  of activation for boundary migration from the experimental constants  $G_0$  and  $Q_G$ , a value must be assigned to the "free energy"  $\Delta F$  driving primary recrystallization. It has been pointed out<sup>12</sup> that  $\Delta F$  cannot be evaluated by the methods of classical thermodynamics. However, it seems reasonable to assume that the driving energy for recrystallization is of the same order of magnitude as the energy stored in cold working,  $Z$ . According to the measurements of Taylor and Quinney<sup>13</sup> the maximum stored energy for metals  $Z_m$  is of the order of 25 to 50 cal per g atom and is usually reached at strains of 0.7 or more. For strains,  $\epsilon$ , of the order of magnitude ( $\sim 0.10$ ) of those for which  $G$  values in recrystallization are known, it may be assumed that  $Z = Z_m \epsilon/0.7$  and for most experimental conditions that are encountered in primary recrystallization:

$$Z_m \epsilon/0.7RT \sim \Delta F/RT \sim \epsilon \times 10^{-1.5 \pm 1}$$

It seems probable that  $\Delta F$  must be less than  $Z$  because of recovery prior to boundary migration. Due to the uncertainty in  $\Delta F/RT$  the calculated  $(\Delta F_A)_G$  may be in error by as much as  $\pm 2$  kcal per g atom.

In developing the theory it is assumed that the driving energy is uniformly distributed in the cold-worked matrix. More information about the state of the cold-worked matrix is needed to test this assumption. Bragg<sup>14</sup> and Heidenreich<sup>15</sup> have suggested that the cold-worked state of a crystal may consist of an aggregation of small misoriented blocks demarcated by intersecting slip planes. If it is further supposed that the strain energy is proportional to the surface area of these blocks, the theory of boundary migration driven by strain

\* Given data on synthetic crystal expressed as stress. Strains estimated from stress-strain curve on natural crystals.

\*\* From data on self-diffusion on pure iron.<sup>23</sup>

energy is analogous to that driven by surface energy, where it is correct to suppose that  $\Delta F$  is uniformly distributed.

Data are available giving  $G$  as a function of temperature and strain in the primary recrystallization of some lightly deformed polycrystalline metals<sup>18-20, 1</sup> and more heavily deformed single crystals of rock salt.<sup>20</sup> The entropy  $(\Delta S_A)_G$  and free energy  $(\Delta F_A)_G$  of activation for grain boundary migration have been calculated from these data and are compared with the entropy  $(\Delta S_A)_L$  and free energy  $(\Delta F_A)_L$  of activation for lattice self-diffusion in Table Ia. In all cases  $\Delta F_A$  was calculated at the average temperature in the range of measurements.

Since no self-diffusion data for aluminum are available,  $Q_L$  was calculated from the empirical relation<sup>24</sup> discovered by Steigman, Shockley, and Nix<sup>22</sup> that  $Q_L \sim 0.7$  times the heat of sublimation.  $D_o$  was estimated from this value of  $Q_L$  using the Dushman-Langmuir equation.  $D_L$  for rock salt was calculated from the anion (slowest moving ion) conductivity data<sup>21</sup> using eq 5. The grain boundary thickness and diffusion distance  $\lambda$  were assumed to be  $2 \times 10^{-8}$  cm in all cases.

**Secondary Recrystallization:** Suppose that a large grain of dimension  $l$  grows into a recrystallized matrix having a small grain size  $l_o$ . Let the grain boundary free energy between matrix grains be  $\sigma$  and that between the large grain and the matrix be  $\sigma'$ . Then if the grain growth is driven by surface tension forces only  $\Delta F$  between the large grain and the matrix grains is given by:

$$\Delta F = KV (\sigma/l_o - \sigma'/l) \quad [14]$$

where  $K$  is a geometric factor of the order of unity and  $V$  is the gram-atomic volume of the material. When secondary recrystallization becomes perceptible  $l \gg l_o$ ,  $\sigma/l_o \gg \sigma'/l$  and eq 14 becomes:

$$\Delta F = KV\sigma/l_o \quad [15]$$

$G$  has been measured in the secondary recrystallization of copper<sup>2</sup> and silver.<sup>3</sup> The absolute grain boundary free energy in copper has been measured absolutely in several investigations.<sup>25-27</sup> The results have been summarized by Fisher and Dunn<sup>28</sup> who suggest 600 ergs per sq cm at 800°C as the best value for grains of large orientation difference. Assuming typical experimental conditions in the secondary recrystallization of copper to be  $l_o = 0.01$  cm and  $T = 1000^\circ\text{K}$  it follows:<sup>\*</sup>

$\Delta F/RT = K\sigma V/l_o RT \sim 10^{-5 \pm 1}$ . It can be assumed that  $\Delta F/RT$  in the secondary recrystallization of silver is also  $\sim 10^{-5 \pm 1}$ .  $(\Delta S_A)_G$  and  $(\Delta F_A)_G$  for secondary recrystallization calculated on the basis of these assumptions are compared with the corresponding constants for lattice and grain boundary self-diffusion in Table Ib.

**Normal Grain Growth:** Experimental data on normal grain growth are available from which  $d\bar{l}/dt$  may be calculated as a function of temperature and grain size. Thus far it has not been possible to deduce from this data the velocity of migration of particular boundaries driven by a known free energy. For the purposes of the present calculation it will be assumed that: 1— $d\bar{l}/dt = G$ ; and 2—

\* Because of the small orientation differences of neighboring grains  $\sigma < 600$  for cube texture copper. However, in view of the sharp increase in  $\sigma$  with increasing misorientation,  $\theta$ ,<sup>28</sup> an uncertainty no greater than a factor of 2 results from assuming  $\sigma \sim 600$ .

† The comparisons were not made for  $\alpha$  brass because of the uncertainty in the interpretation of the diffusion data.

Fig. 3—Free energy of activation as a function of strain,  $\epsilon$ , in the primary recrystallization of polycrystalline aluminum<sup>1</sup> and rock salt single crystals.<sup>20</sup>

$\Delta F = K\sigma V/\bar{l}$  in normal grain growth.  $(\Delta F_A)_G$  calculated with these assumptions will be too large, possibly by 2 to 4 kcal per g atom. However, it will be seen that this uncertainty in  $(\Delta F_A)_G$  does not affect the validity of the general conclusion drawn from the calculations. The values of the entropy and free energy of activation in normal grain growth are summarized in Table Ic.

**Interpretation of the Results:** The most important conclusion that follows from the comparisons made in Table I is that the free energy of activation for self-diffusion within a crystal exceeds the free energy of activation in boundary migration by a large amount (10 to 25 kcal per g atom) that is much greater than the uncertainties in the calculation in all cases.† From this result it follows that the atomic mobility in grain boundary migration,  $M_G$ , is always larger by many orders of magnitude than the atomic mobility in lattice self-diffusion  $M_L$ ; e.g., in the secondary recrystallization of OFHC copper at 950°C,  $M_G = 10^8$  compared to  $M_L = 10^{3.8}$ .

There is good reason to expect that the grain boundary regions in metals are highly disordered relative to regions within the body of the crystal. Since it is further supposed that diffusion is promoted by crystal imperfections, it is not surprising that  $M_G \gg M_L$ . However, this result is not obvious from comparing  $Q_L$  with  $Q_G$  for  $Q_L$  is sometimes smaller, about the same, or larger than  $Q_G$ .

Data on the rate of self-diffusion at grain boundaries are available only for silver,<sup>29</sup> and it may be very significant that the free energy of activation  $(\Delta F_A)_B$  agrees closely with the free energy of activation  $(\Delta F_A)_G$  in the secondary recrystallization of silver. This fact suggests the possibility that the generalization  $(\Delta F_A)_B = (\Delta F_A)_G$  holds for grain boundary migration processes driven by interfacial tension. The results also suggest that the generalization  $(\Delta F_A)_B \cong (\Delta F_A)_G$  holds for primary recrystallization.

$(\Delta F_A)_G$  at 625°K as a function of strain has been calculated for Anderson and Mehl's<sup>1</sup> data on the primary recrystallization of aluminum and plotted in Fig. 3. For  $0.2 > \epsilon > 0.05$ ,  $(\Delta F_A)_G$  is independent of  $\epsilon$ . However, between  $\epsilon = 0.02$  and  $0.05$   $(\Delta F_A)_G$  decreases about 2 kcal per g atom, a number that is about 1000 times larger than the stored energy of cold working,  $Z$ . Also shown in Fig. 3 is  $(\Delta F_A)_G$  vs.  $\epsilon$  calculated from Muller's data<sup>20</sup> on the primary recrystallization of rock salt crystals at 600°C. It is evident that  $(\Delta F_A)_G$  is much more strain-sensitive for rock salt single crystals than for polycrystalline aluminum.

It might be inferred from inspection of the constants  $Q_G$  and  $(\Delta S_A)_G$  that the  $G$  values in the three investigations on aluminum are in wide disagreement. Actually  $(\Delta F_A)_G$  values for the temperatures

Fig. 4—Representation of  $\log G$  vs.  $1/T$  for various degrees of dispersion ( $I$ ) of inclusions at grain boundaries.

at which the measurements nearly overlap approximately agree. At  $400^\circ\text{C}$  for  $\epsilon = 0.05$ , Anderson-Mehl's<sup>1</sup> results give  $(\Delta F_A)_G = 18.0$  compared to 19.0 kcal per g atom obtained by Kornfeld-Pavlov<sup>17</sup> for  $\epsilon = 0.04$ . These values are in reasonable agreement with  $(\Delta F_A)_G = 24.5$  kcal per g atom for normal grain growth in aluminum at  $400^\circ\text{C}$ <sup>30</sup> in view of the fact that the theory as now formulated gives too large a value to  $(\Delta F_A)_G$  in normal grain growth.

Though the atomic mobility in grain boundary migration is many times larger than in lattice self-diffusion, the activation energy for the former process is often as great and sometimes even greater than for the latter process. These relations are consistent with the fact that the entropy of activation in boundary migration is generally 10 to 30 entropy units larger than in lattice self-diffusion. On the basis of the arguments used to account for  $(\Delta F_A)_L > (\Delta F_A)_G$ , it would be expected that  $Q_L > Q_G$ . Also there is no obvious reason for the entropies of activation for the two processes to be very different.

In order to account for these seeming anomalies Mott<sup>9</sup> has proposed the hypothesis that activation for grain boundary migration consists in melting several ( $n$ ) atoms at the boundary. According to this view the energy of activation for boundary migration is the energy necessary to fuse  $n$  atoms:

$$Q_G = nQ_f \quad [16]$$

where  $Q_f$  is the gram-atomic heat of fusion and may therefore bear no simple relation to  $Q_L$  (or  $Q_B$ ). On this picture the entropy of activation is the entropy gain in melting  $n$  atoms:

$$(\Delta S_A)_G = n\Delta S_f \quad [17]$$

where  $\Delta S_f$  is the entropy of fusion.<sup>‡</sup>  $n$  may be a function of strain, temperature and relative grain and boundary orientations. Mott's theory reduces the number of disposable parameters from  $(\Delta S_A)_G$  and  $Q_G$  to  $n$  only and can be tested by comparing  $(\Delta S_A)_G$  with  $n(\Delta S_f)$  where  $n$  is calculated from  $Q_G$  using eq 16. Mott showed that the theory accounts for the entropy of activation calculated from Anderson's and Mehl's data on aluminum and Smoluchowski<sup>30</sup> has shown that the theory accounts for the grain growth data of Beck, Holzworth, and Hu<sup>30</sup> on pure aluminum and of Burke<sup>31</sup> on  $\alpha$  brass of commercial purity.

In order to make a comparison of  $n\Delta S_f$  and  $(\Delta S_A)_G$  strictly in conformity with Mott's theory, it is necessary to modify the calculation of  $(\Delta S_A)_G$  by substituting  $n\Delta F$  for  $\Delta F$  in eq 11, since  $n$  atoms are transported in the elementary process. The values of the entropy of activation for boundary migration  $(\Delta S_A)_G'$  so calculated from all the available data are compared with  $n\Delta S_f$  and  $(\Delta S_A)_L$  in Table II.

Though  $(\Delta S_A)_G'$  and  $n\Delta S_f$  diverge widely in a few

<sup>‡</sup> Mott's formulation has been altered somewhat in order to make it conform to the absolute rate theory.

instances the comparisons in Table II indicate that Mott's theory in general successfully accounts for the unexpectedly large values of  $(\Delta S_A)_G'$ . In addition to the divergences noted the main objection to the theory as it now stands is the arbitrariness of the  $n$  values. Also in view of the small values of  $n$  ( $< 35$ ) it is not correct to ignore surface energy considerations in calculating the free energy of melting. On an energetic basis  $n$  should be unity if the surface energy is neglected.

One of the basic assumptions of the theory developed is that the driving energy does not change with temperature. An alternative theory for the large magnitude of the calculated  $(\Delta S_A)_G$  values is that they are more apparent than real due to a marked dependence of  $\Delta F$  upon temperature.  $\Delta F$  might change markedly with temperature due to matrix processes of recovery, grain growth, or solution of boundary retarding inclusions concurrent with boundary migration. Among these processes only the solution of inclusions is likely to lead to apparent values of  $(\Delta S_A)_G$  that are much greater than the actual values.

Following Zener<sup>32</sup>  $\Delta F$  for boundary migration retarded by inclusions may be expressed as:

$$\Delta F = (\Delta F' - K\sigma\rho V/\gamma_o) = \Delta F' - I \quad [18]$$

where  $\Delta F'$  is the driving free energy in the absence of inclusions,  $\rho$  is the volume fraction of inclusions in the matrix, and  $\gamma_o$  is the radius of the inclusion. In general  $I$  is likely to be a function that decreases with increasing time or temperature. However, suppose that at constant temperature  $I$  reaches a constant value in a time that is short relative to the period of boundary migration. Then with respect to boundary migration,  $I$  is a function of temperature only and  $G$  is independent of time. In Fig. 4  $\log G$  is represented schematically as a function of  $1/T$  for various constant values of  $I$ , each characteristic of a different temperature. This family of curves all have the same value of  $Q_G$ , but apparently different values of  $(\Delta S_A)_G$  that may be quite small. However, since  $I = f(T)$  the observed relation for  $\log G = f(1/T)$  will be schematically as shown by the solid curve through the circles and the apparent values of  $Q_G$  and  $(\Delta S_A)_G$  will be much larger than those characteristic of  $I = 0$ .

The inclusion hypothesis predicts that  $Q_G$  and  $(\Delta S_A)_G$  may decrease as temperature increases due to the progressive solution of inclusions. Ward<sup>2</sup> has found that  $Q_G$  and  $(\Delta S_A)_G$  do markedly decrease in the secondary recrystallization of cube texture copper as the melting point is approached. Also the results of Burke<sup>31</sup> show that  $Q_G$  and  $(\Delta S_A)_G$  for grain growth are much smaller for high purity than for commercial purity  $\alpha$  brass.

In primary recrystallization  $\Delta F'$  probably is very much larger with respect to  $I$  than in boundary migration processes driven by surface energy. Suppose that it is known that primary recrystallization occurs at a given temperature,  $T_1$ , at a strain of 0.02. Then if  $Z$  is proportional to  $\epsilon$ , as assumed, the inclusions should have a negligible effect in retarding boundary migration at  $T_1$  for a strain of 0.10. Thus, unless the strain energy is greatly reduced by recovery processes, inclusions should be effective in retarding boundary migration in primary recrystallization only when  $\epsilon$  is very small and  $(\Delta S_A)_G$  and  $Q_G$  calculated when  $\epsilon$  is relatively large should approach the real values. In the recrystallization of rock salt single crystals  $(\Delta S_A)_G$  and  $Q_G$  are very

\* Entropy and heat of fusion calculated by atomic fraction averaging of corresponding constants for pure metals.

large for small strains (see Table I) and fall sharply as the strain is increased. More direct support for the hypothesis that inclusions often significantly retard boundary migration in primary recrystallization as well as in normal grain growth is furnished by the observations of Muller<sup>20</sup> that the boundaries move in spurts in the primary recrystallization of rock salt.
